Linopirdine is a relatively specific M-current inhibitor and was shown to enhance learning and cognition in a mouse model [111] but failed to show a clear affect in a human Alzheimer's disease trial [112]. The M current is also blocked by XE991, though this drug inhibits KCNQ1 and KCNQ4 as well. An activator of KCNQ2/3, retigabine, is in clinical trials as an anticonvulsant to treat epilepsy and may also be useful in treating neuropathic pain [113]. The BK activator BMS-204352 also stimulates M current.

14.2.7.6 KCNH K^+ Channels. Channels of the KCNH family include EAG, HERG, and ELK. These names derive from the channels' homology to the *Drosophila ether-à-go-go* channel and are characterized by their slow activation and direct activation by cyclic nucleotides. Another important property of these channels is that they are voltage dependent and activate at subthreshold or near-threshold potentials, suggesting that they could play a role in resting membrane potential regulation [114] and spike frequency adaptation [115]. HERG is best known for its role in the fast delayed rectifier current (I_{Kr}) of the cardiac action potential, where it carries a large portion of the outward current during repolarization. The channel has an unusual, bell-shaped current–voltage curve, with increasing currents up to +10 mV, then progressively smaller currents at more depolarized potentials [116]. This behavior is the result of slow voltage activation coupled with unusually fast C-type inactivation at depolarized potentials [117]. Mutations in

HERG are associated with long-QT syndrome, type 2, and account for the reduced potassium currents that lead to prolongation of the cardiac QT phase.

In general, the function of KCNH channels in the mammalian nervous system is not well characterized, despite the well-studied role of these channels in *Drosophila* neuromuscular function. ERG mRNA is present throughout the brain [118] and has been suggested to play a role in firing frequency and spike frequency adaptation in cerebellar Purkinje neurons [119]. The three ELK channels have predominantly neuronal expression and can coassemble with one another. Although their functional importance is unknown, their activation at potentials near the resting potential suggests a role in neuronal excitability. EAG channels are expressed predominantly in nonneuronal tissues and are notably upregulated in various tumors. Transfection of normal cells with the gene encoding EAG can lead to transformation to tumor cells [120], and EAG expression has been reported to be a marker for cervical cancer [121]. HERG also has oncogenic potential in neoplastic hematopoietic cells [122]. This unexpected role for ion channels in cell proliferation is likely related to cell cycle-dependent changes in channel activity [123].

The rapid delayed rectifier potassium current of the heart, I_{Kr} , is a major drug target for the treatment of arrhythmia, and the class III methanesulfonamide antiarrhythmics block this current carried by HERG/KCNE2. The methanesulfonamides include dofetilide, E-4031, ibutilide, D-sotalol, and MK-499. They are open channel blockers that enter the cytoplasmic mouth of the channel and bind to residues in the central cavity [124]. Class III antiarrhythmics prolong the ventricular action potential by increasing the QT phase. While these drugs can work by pore block, there are also reports that they can rescue channel mutants with folding defects and increase trafficking to the plasma membrane [125]. Unfortunately, many of these drugs are associated with drug-induced long-QT syndrome, an increased risk for torsade de pointes, and sudden cardiac death [126]. Still, the class III antiarrhythmics are useful as a therapy for atrial fibrillation or flutter [127].

Antihistamines (astemizole, terfenadine), antipsychotics (chlorpromazine, haloperidol), some antibiotics, and gastrointestinal prokinetic agents (cisapride) have also been found to cause drug-induced long-QT syndrome and ventricular arrhythmia [126]. Peptide toxins that block other voltage-gated K^+ channels are generally not effective against HERG, but recently two scorpion peptides, Ergtoxin and BeKm-1, have been identified and specifically inhibit HERG but not ELK or EAG channels [128, 129].

Although relatively little is known about EAG and ELK pharmacology relative to HERG's, EAG is a potential target for antitumor therapies, as both the antihistamine astemizole [130] and the tricyclic antidepressant imipramine [131] can inhibit EAG-mediated cell proliferation. The physiological roles of ELK channels are still unknown, and the search for their function would be aided by specific pharmacological tools.

14.2.8 Other Subfamilies of K^+ Channels: Inwardly Rectifying and Two-P K^+ Channels

The inwardly rectifying subfamily contains the basic TM unit of a K^+ channel, two TMSs flanking the P loop. The unique electrophysiological feature of these channels is inward rectification: a larger conductance at membrane potentials favoring inward current than at potentials favoring outward current. This property is the result of blockade of the cytoplasmic side of the pore by magnesium or polyamines at

depolarized potentials. These channels are open around the resting potential and resist small depolarizations but are blocked upon stronger depolarizations, such as those following the opening of voltage-gated Na^+ channels.

Inwardly rectifying K^+ channels help to set the resting membrane potential of excitable cells and play more specialized roles than other cell types. The ATP-inhibited K_{ATP} channel, for example, is an octamer of four Kir 6.1 or 6.2 subunits and four sulfonylurea receptor (SUR) subunits. Inhibition of K_{ATP} in pancreatic β cells promotes insulin release. Another class of inward rectifier is the protein-coupled inwardly rectified K^+ (GIRK) channels, which are opened by binding to the G-protein $\text{G}_{\beta\gamma}$ subunit and so are linked to the activity of G-protein-coupled receptors.

The two-P, or KCNK, channels [132] have only recently been identified and make up a subfamily of 14 members in humans. Their topology consists of two inward rectifier channels linked in tandem, so they contain two P loops per subunit and presumably assemble as dimers. Functionally, the two-P channels are thought to carry background, or leak, potassium conductances which set the resting potential of many cell types and can modulate the excitability of neurons, heart and muscle cells, and endocrine cells. While no high-affinity, specific agents for two-P channels have been identified, a number of physiological stimuli, such as mechanical stretch, acid, and polyunsaturated fatty acids, do affect channel open probability. Some neurotransmitters can inhibit two-P channels, further enhancing membrane excitability through second-messenger pathways [133]. Two-P channels may also be a target for general anesthetics, as agents such as halothane and chloroform open some KCNK channels at clinically relevant concentrations [134].

14.3 VOLTAGE-GATED SODIUM CHANNELS

Voltage-gated Na^+ channels and K^+ channels are responsible for action potential generation. In the initial phase of a neuronal action potential, small inward currents through postsynaptic ligand-gated cation channels sum to produce a threshold depolarization. This depolarization activates a large inward sodium current that depolarizes the cell even further and then inactivates within several hundred milliseconds. Voltage-gated Na^+ channels carry this large inward current, spreading the depolarization from the axon initial segment, to the nodes of Ranvier along the axon and ultimately to the nerve terminal where neurotransmitter release occurs. By contrast, voltage-gated K^+ channels are responsible for the repolarization of the membrane: They open after voltage-gated Na^+ channels and carry a large, opposing outward current that returns the membrane potential toward its resting value, reverses Na^+ channel inactivation, and allows the neuron to fire another action potential.

For repetitive neuronal firing to be possible, voltage-gated Na^+ channels must be highly selective for sodium over other ions, must open rapidly in the correct range of membrane potential, must inactivate quickly, and then must recover upon membrane repolarization. In addition, the channels must be targeted to the correct subcellular locations, such as the axon initial segment and nodes of Ranvier. Voltage-gated Na^+ channels are expressed in excitable cells of the central and peripheral nervous systems, the heart, and skeletal muscle as well as several other excitable cell types. They have been found in many animal species, both vertebrates and invertebrates,

though they are absent in the nematode *Caenorhabditis elegans*. Recently, a superfamily of bacterial voltage-gated Na^+ channels has even been identified, though these Na^+ channels resemble voltage-gated K^+ channels in topology rather than their mammalian sodium-selective counterparts [6, 135].

In their groundbreaking electrophysiological studies of the squid giant axon, Hodgkin and Huxley measured sodium- and potassium-selective conductances [136] but did not yet know what cellular components mediated these ionic fluxes or if they were even separate entities. The discovery of two toxins that could inhibit the axonal sodium current but not the potassium current, tetrodotoxin (TTX) from puffer fish and saxitoxin from *Gonyaulax* marine dinoflagellates, gave the first strong evidence that sodium and potassium traversed the membrane through distinct pathways [137, 138].

A voltage-gated Na^+ channel from the electric eel *E. electricus* was the first voltage-gated ion channel to be cloned [1], and its primary structure immediately provided clues to the function of the channel. The channel is made up of four homologous repeats ($\text{D}_{\text{I-IV}}$) of six putative TMSs (Fig. 14.1a), each repeat having a cluster of positively charged residues that were proposed to be part of the voltage-sensing mechanism. The fourth TMS (S4) of each repeat has a positively charged residue approximately every fourth residue, while the determinants of ion selectivity are residues in the region between the S5 and S6 TMS (the SS1–SS2 region). The S6 transmembrane domain lines the ion conduction pathway. Inactivation of the channel appears to be mediated by an interaction between the linker between the third and fourth repeats of the Na^+ channel and the cytoplasmic ends of the S5 and S6 TMS [139, 140].

The cytoplasmic N- and C-terminal domains of the Na^+ channel, as well as cytoplasmic linker regions between the repeats, provide sites for posttranslational modifications and coassembly with cytoplasmic domains of other proteins. Mutations in many parts of the channel can interfere with the electrophysiological function or the targeting of voltage-gated Na^+ channels and lead to a number of cardiac, neurological, and skeletomuscular disorders. In the following sections, we will discuss in more detail the molecular basis for the electrophysiological and cell biological properties of voltage-gated Na^+ channels, their physiological significance in both normal and disease states, and the pharmacology of voltage-gated Na^+ channels.

14.3.1 Single Family of Voltage-Gated Na^+ Channel α Subunits

The mammalian repertoire of voltage-gated Na^+ channels consists of 10 members which are so closely related that they make up a single family (Fig. 14.2a). This is in contrast to voltage-gated K^+ channels, which can be divided into at least 12 subfamilies, and the three subfamilies of voltage-gated Ca^{2+} channels. Nine of the α subunits, $\text{Na}_v1.1$ – 1.9 , have more than 70% identity in the TM and extracellular amino acids, while the tenth channel, Na_x , is approximately 50% identical to the other nine Na^+ channels but has sequence differences in some of the key regions for selectivity, voltage sensing, and inactivation.

The brain Na^+ channel was originally isolated as a trimer of the pore-forming α subunit $\text{Na}_v1.2$ with the β_1 and β_2 auxiliary subunits [141], but in other tissues the α subunits may interact with only one or none of the cloned β subunits. There are four β subunits, of which two, β_2 and β_4 , form disulfide bonds with the α subunit; β_1 and β_3 interact noncovalently with the α subunit. These proteins have a single TMS, a

short cytoplasmic domain, and a heavily glycosylated extracellular domain. The extracellular domain has an immunoglobulin G (IgG)-type fold that is homologous to several cell adhesion proteins and is thought to mediate clustering of channels with other proteins at nodes of Ranvier and the axon initial segment as well as cell-cell contact. In addition to affecting the subcellular localization of voltage-gated Na^+ channels, β subunits can also modulate the electrophysiological properties of α subunits, such as the rate of fast inactivation and voltage dependence of activation. The effects of β subunits may help to explain functional differences between heterologously expressed α subunits and native channels.

All members of the voltage-gated Na^+ channel family share the same topology, with four pseudorepeats, each containing six putative TMSs, and cytoplasmic N- and C-termini. The fourth TMS of the first three repeats has four to five lysines or arginines, while the S4 of the fourth repeat has seven to eight positively charged residues. Current models suggest that all four S4 segments shift toward the extracellular side of the membrane during voltage activation [142]. A number of studies of the gating charge indicate that the positively charged residues may be mostly surrounded by water-filled crevices such that the entire TM electric field is compressed into a distance of a few angstroms [143]. Accordingly, relatively modest translations of the S4 segments may be sufficient to carry the entire gating charge.

14.3.2 Selectivity

While K^+ channel selectivity is determined by backbone carbonyl coordination of ions in the selectivity filter, it is charged side chains in the Na^+ channel pore that appear to be crucial for selectivity. Voltage-gated Na^+ channels are approximately 10-fold more selective for sodium over potassium and have a negligible permeability to calcium. The SS1–SS2 region of the four repeats has a conserved set of residues, D (repeat I), E (repeat II), K (repeat III), and A (repeat IV), known as the DEKA region (Fig. 14.1a). These four residues are thought to form a ring of side chains that allow for sodium permeation while excluding potassium and calcium. Mutation of the pore lysine residue of the DEKA motif eliminates the channel's selectivity among alkali metal ions and makes the channel permeable to calcium and even to large organic cations such as TEA [144]. Ca^{2+} channels have four glutamate (E) residues at the equivalent positions, and in fact, a Na^+ channel can be converted to a Ca^{2+} channel by mutating the D, K, and A of the DEKA region to glutamates [145]. Voltage-gated K^+ channels are presumed to have a fourfold rotationally symmetric pore, since they are composed of four equivalent monomers, and the coordination of potassium resembles the geometry of a hydrated potassium ion [146]. By contrast, the Na^+ channel pore clearly uses the asymmetry afforded by four nonequivalent repeats in order to discriminate among ions.

14.3.3 Inactivation

Na^+ channel inactivation allows for the recovery of the resting membrane potential and for repetitive firing, and many disease mutations of Na^+ channels affect this aspect of channel activity. Voltage-gated Na^+ channel inactivation can be divided into a fast inactivation, which occurs within milliseconds of channel opening, and slow inactivation, which occurs on a time scale of hundreds of milliseconds to

minutes. Although inactivation depends on voltage activation of the channel, inactivation itself does not require the voltage-gated migration of any charged residues [147]. Rather, it appears to be a conformational change that leads to blockage of the conduction pore by a cytoplasmic region between the third and fourth repeats of the channel.

Fast inactivation of voltage-gated Na^+ channels is essential for proper firing of action potentials and for preventing backward propagation of action potentials along the axon. It limits the duration of the depolarization mediated by sodium influx and gives a directionality to the action potential: Once the Na^+ channels at a given node of Ranvier have opened and inactivated as part of an action potential, the action potential will propagate only in the direction of open Na^+ channels, toward the axon terminal. Three residues in the III–IV linker region are critical for inactivation and have been termed the IFM (isoleucine–phenylalanine–methionine) motif (Fig. 14.1a) [139, 148]. These residues likely dock to the inner mouth of the channel, since mutations of residues in the cytoplasmic end of the DIV S6 TMS [149] and in the DIV S4–S5 loop [150] can disrupt fast inactivation.

While fast inactivation directly affects action potential duration, slow inactivation plays a role in spike frequency adaptation and may even be important for memory of previous channel activity [151]. Near the resting potential, very few channels undergo fast inactivation, but slow inactivation can be a factor in regulating the duration of openings in this range. Thus, slow inactivation can decrease membrane excitability by keeping voltage-gated Na^+ channels closed in the steady state. The P region, or SS1–SS2, appears to be important for slow inactivation, since a residue in this part of the h $\text{Na}_v1.5$ (D_{II}) was found to be a critical determinant of the probability of entry into a slow-inactivated state [152]. As is the case with voltage-gated K^+ channels, voltage-gated Na^+ channel slow inactivation may be due to a collapse of the pore in response to other conformational changes within the channel.

14.3.4 Trafficking

A well-characterized example of voltage-gated Na^+ channel trafficking is the localization of $\text{Na}_v1.2$ at the axon initial segment of neurons. Although the β subunits are involved in adhesion and channel trafficking, they do not themselves target Na^+ channels to the axon. Rather, the α subunit contains several motifs that allow for its proper localization. A dileucine motif in the C-terminal domain is responsible for internalization of the channel in somadendritic membrane but not axonal membrane [153]. Axonal channels may be trapped by the ankyrin G– β -IV spectrin complex, while the Na^+ channels in nonaxonal membrane are untethered and retrieved by endocytosis [154]. While the C-terminus is sufficient for axonal targeting, it cannot localize $\text{Na}_v1.2$ at the initial segment of the axon. The channel has an acidic cluster in the cytoplasmic II–III linker that acts as a retention motif for the axon initial segment [155]. This motif binds to the clustering protein ankyrin G and is conserved in $\text{Na}_v1.1$, 1.3, 1.4, 1.5, and 1.6.

Interactions between ankyrin G and β -spectrin help Na^+ channels to cluster at high density in the postsynaptic membrane of neuromuscular junctions [156]. Ankyrin G is also essential for targeting of voltage-gated Na^+ channels to the axon initial segment and nodes of Ranvier, as mice with ankyrin G knocked out fail to properly localize axonal Na^+ channels [157]. Neurofascin and NrCAM are cell

adhesion proteins that cluster with ankyrin G at the axon initial segment and are important for Na^+ channel accumulation at nodes of myelinating cells [158]. Cell adhesion molecules prevent channels from diffusing away from nodes of Ranvier and the axon initial segment.

14.3.5 Physiological Functions

Of the nine members of the $\text{Na}_v1.x$ family, seven are expressed in the central and/or peripheral nervous system; $\text{Na}_v1.5$ is found primarily in heart muscle and $\text{Na}_v1.4$ is localized to skeletal muscle cells. Na_x has a wider distribution and has been identified in heart, uterus, glia, the peripheral nervous system, and smooth muscle.

Within neurons, Na^+ channels are often localized at the axon initial segment and nodes of Ranvier, where they play an essential role in the propagation of action potentials. These channels generally carry transient, fast-inactivating sodium currents that allow for rapid recovery and repetitive firing of neurons. Somatic integration of excitatory synaptic inputs causes action potential initiation at the axon initial segment. The insulating properties of myelin allow the action potential to jump rapidly from node to node and ultimately to the synaptic terminal, where the opening of voltage-gated Ca^{2+} channels stimulates neurotransmitter release.

Although some voltage-gated Na^+ channels are selectively retrieved from somatodendritic membrane, Na^+ channels are still present in dendrites. At post synaptic dendritic sites, Na^+ channels may amplify excitatory postsynaptic potentials as they travel toward the soma. In addition, action potentials can backpropagate from the soma to the dendrites, and the efficiency of backpropagation is dependent on the dendritic Na^+ channel density [159]. In Purkinje neurons, for example, dendritic Na^+ channel density decreases steeply with distance from the soma [160], so backpropagating action potentials dissipate quickly. In mitral cells or hippocampal CA1 neurons [159, 161], however, there is a higher ratio of Na^+ to K^+ channels in the dendrites, allowing for regenerative action potential backpropagation. The coincidence of subthreshold postsynaptic stimulation and backpropagating action potentials is thought to underlie some forms of synaptic plasticity. The calcium influxes mediated by this coincidence could mediate long-term potentiation (LTP) and other transcriptional changes in neuronal activity.

While the best characterized voltage-gated sodium currents are transient and fast inactivating (Fig. 14.4b), sodium currents with different inactivation properties are important for modulating excitability. Persistent sodium currents (Fig. 14.4b) are present at subthreshold potentials, where channels can open but fast inactivation does not occur. Their activation can effectively depolarize the cell such that it is closer to the threshold for action potential firing. More substantial depolarization by a persistent sodium current, however, can lead to resting inactivation of Na^+ channels and decreased excitability. This distinction underlies the ability of some skeletal muscle Na^+ channel mutations that disrupt fast inactivation to cause myotonia (hyperexcitability), while others cause paralysis (hypoexcitability). Inhibiting persistent sodium currents also decreases excitability as K^+ channels that are open at rest push the membrane toward more hyperpolarized potentials. Persistent currents have been found electrophysiologically in central [162] and peripheral neurons [163] and are thought to be mediated by $\text{Na}_v1.6$. There are other reports of TTX-resistant persistent sodium currents as well [164].

In addition to the rapidly inactivating and persistent sodium currents, a resurgent sodium current has also been characterized [165]. It appears after a large depolarization, such as an action potential, followed by a return to a slightly depolarized potential (-40 mV). The resurgent current increases slowly and decays slowly and might facilitate repetitive firing. The molecular identity of this current is not known, though mice lacking $\text{Na}_v1.6$ also lack the resurgent current [166].

Several Na^+ channel family members are expressed predominantly in the peripheral nervous system, particularly in sensory neurons, and are thought to play a role in pain sensation. The Na^+ channel-blocking activity of local anesthetics provides further evidence for the role of voltage-gated sodium currents in nociception. $\text{Na}_v1.7$ is expressed at the terminal of sensory neurons, while $\text{Na}_v1.8$ is exclusively expressed in sensory, especially nociceptive, neurons. Both channels respond to inflammatory factors involved in hyperalgesia, like nerve growth factor (NGF) [167, 168], which increases expression of these channels in response to tissue damage and leads to inflammatory pain sensation. Primary erythromalgia, a chronic human inflammatory disorder, which causes intermittent extreme pain and redness in the feet and hands, maps to the $\text{Na}_v1.7$ locus [169], and the associated mutations lead to hyperexcitability of nociceptive dorsal root ganglion (DRG) neurons [170]. Accordingly, mice with $\text{Na}_v1.7$ deleted from sensory neurons have increased mechanical and thermal pain thresholds and decreased inflammatory pain responses [171]. $\text{Na}_v1.8$ is also likely to play a role in inflammatory pain on account of its upregulation by NGF and the analgesic effects of $\text{Na}_v1.8$ antisense in models of inflammatory pain [172].

$\text{Na}_v1.3$ is generally expressed in the adult central nervous system, but upon nerve damage such as axotomy this channel and the β_3 subunit can be upregulated in sensory neurons [173]. This expression of $\text{Na}_v1.3$ may be an important cause of hyperexcitability and neuropathic pain following nerve injury. Its upregulation can be suppressed by glial-derived neurotrophic factor (GDNF) [174], a factor associated with analgesia. $\text{Na}_v1.9$, by contrast, provides a persistent sodium current that is downregulated after axotomy [175]. Since $\text{Na}_v1.9$ is activated at more hyperpolarized potentials compared to other Na^+ channels and has relatively slow kinetics of activation and inactivation [164], a decrease in its expression could remove resting inactivation of other Na^+ channels and thereby increase excitability. Thus, activation of $\text{Na}_v1.9$ might be an effective way to minimize neuropathic pain.

In the central nervous system, changes in the localization of neuronal channels in myelinated neurons may play a role in the degenerative processes of multiple sclerosis (MS). $\text{Na}_v1.6$ is usually localized to the nodes of Ranvier, but its distribution throughout the axon becomes more diffuse during the demyelination characteristic of MS. $\text{Na}_v1.6$ is also upregulated and colocalizes with the sodium–calcium exchanger as well as with β -amyloid precursor protein, a marker for axonal damage, in MS-damaged neurons. The persistent current mediated by $\text{Na}_v1.6$ may cause increased calcium influx into the cell via the sodium–calcium exchanger and thus provide a mechanism for toxicity [176].

The predominant voltage-gated Na^+ channel subunit in heart cells is $\text{Na}_v1.5$, which plays a key role in the depolarization and plateau phases of the cardiac action potential. A number of arrhythmias and other cardiac diseases are due to mutations in $\text{Na}_v1.5$, and drugs from the class I antiarrhythmics are blockers of the heart voltage-gated Na^+ channel. Brain Na^+ channels $\text{Na}_v1.1$ and 1.3 have also been

identified in the sinoatrial node of the heart, where no $\text{Na}_v1.5$ is expressed. The associated currents are TTX-sensitive and their blockade results in greater heart rate variability and lower spontaneous heart rate [177].

The $\text{Na}_x \text{Na}^+$ channel has only 50% identity to members of the $\text{Na}_v1.x$ family and notably has fewer charges in the S4 segments and low conservation of residues in the III–IV linker region that mediates fast inactivation. A mouse with this gene knocked out has a reduced capacity to regulate NaCl intake under both high- and low-salt conditions [178]. Na_x is expressed, among other places, in the circum ventricular organs of the brain, which control salt and water homeostasis, consistent with its role in osmoregulation.

14.3.6 Channelopathies

Na^+ channels expressed in skeletal muscle, heart, and the nervous system have been implicated in a number of genetic disorders, and Na^+ channel activity plays a role in many other disease states. Inherited mutations that affect channel activity most frequently change the inactivation properties of the Na^+ channel, rendering the cells where they are expressed either more or less excitable than they would normally be. Other mutations affect voltage-dependent activation or assembly with other proteins required for proper channel function.

Mutations in the skeletal muscle Na^+ channel, $\text{Na}_v1.4$, are associated with several channelopathies, including paramyotonia congenita, potassium-aggravated myotonia, hyperkalemic periodic paralysis, and hypokalemic periodic paralysis. Myotonias are characterized by difficulty with muscle relaxation, triggered by exercise, cold, or a rise in plasma potassium levels, and produce repetitive activity in an electromyogram. The most common mutations are T1313M in the III–IV linker and R1448H/C in the S4 of domain IV, both of which slow fast inactivation [179]. Both types of mutations lead to a persistent current that slightly depolarizes muscle cells, enough to decrease the firing threshold but not sufficient to lead to resting inactivation of the Na^+ channel population. Potassium-aggravated myotonia is frequently found to be associated with the G1306E/V/A mutations in the III–IV linker [180]. These mutations in the fast-inactivation loop slow inactivation and lead to a persistent current with more frequent, longer openings.

Periodic paralysis, in contrast to myotonia, is a disorder caused by reduced muscle excitability and is manifested by a silent electromyogram. Hyperkalemic periodic paralysis (HyperPP) can be triggered by stress, fasting, potassium-rich foods, or exercise. The episodic muscle weakness associated with the disorder is the result of incomplete channel inactivation, which leads to a persistent sodium current that can depolarize the resting membrane potential from -90 mV to as high as -50 mV [96 p. 79]. This depolarization causes most of the Na^+ channels to be inactivated at rest and makes them unable to initiate an action potential, explaining the silent electromyogram. Approximately 90% of families with this disorder have a mutation in S6 (D_{II}), T704M, which causes a 10-mV leftward shift in the voltage-dependent opening of the channel [96]. Thus, channels open at more negative potentials, well outside their inactivation range, creating a persistent current that depolarizes the resting membrane potential. Mutations of $\text{Na}_v1.4$ can also lead to hypokalemic periodic paralysis. These mutations lie in D_{II} S4 and enhance both fast and slow inactivation [181].

The cardiac Na^+ channel, $\text{Na}_v1.5$, is associated with several inherited arrhythmic disorders, including long-QT syndrome type 3, Brugada syndrome, and conduction disorder. Long-QT syndrome is caused by a slowed repolarization of the cardiac action potential, manifested by a lengthening of the QT phase of the electrocardiogram. This arrhythmia can lead to lower ventricular filling, ventricular fibrillation, decreased cardiac output, and death. All $\text{Na}_v1.5$ mutations that cause long-QT syndrome type 3 result in defects in fast inactivation [182]. The most severe of these is the $\Delta\text{KPQ1505-7}$ deletion in the III–IV loop [183]. Impaired inactivation prolongs the plateau of the cardiac action potential with a persistent sodium current, resulting in slower repolarization and a QT interval that is 2–5% longer than normal [96]. Class Ib antiarrhythmics such as mexiletine have been used to reduce the persistent sodium current of the mutant channel.

Brugada syndrome [184] is a cardiac arrhythmia that elevates the ST segment of the electrocardiogram, substantially increasing the risk of idiopathic ventricular fibrillation in affected individuals. The elevated ST segment is the result of a voltage gradient between the epicardium and the endocardium: The loss of sodium current has a greater effect on the epicardium, on account of its counteracting the transient outward potassium current ($I_{K_{to}}$), than on the endocardium, where this potassium current is less prominent. The epicardium thus repolarizes prematurely relative to the endocardium, resulting in an arrhythmogenic transmural voltage gradient. Disease mutations are found at amino acids throughout the channel and generally render the channel nonfunctional [185].

In the central nervous system, mutants of both the Na^+ channel α subunit $\text{Na}_v1.1$ and the β_1 subunit have been found to cause generalized epilepsy with febrile seizures. The β -subunit mutation (C121W) maps to a cysteine residue in the extracellular domain that is involved in a disulfide bond which is essential for proper folding of the domain [186]. The α -subunit mutations decrease interaction with β_1 (D1866Y), causing a right shift in the voltage dependence of inactivation and a greater persistent current, or can affect the voltage-dependence of inactivation (I1656M and R1657C) by uncoupling voltage sensor movements from fast inactivation [187–189]. Another form of epilepsy, severe myoclonic epilepsy of infancy (SMEI), has also been mapped to several sites on the *scn1a* ($\text{Na}_v1.1$) gene [190]. Mutants causing this form of epilepsy are either nonfunctional or noninactivating (Fig. 14.4b). Several missense mutations of $\text{Na}_v1.2$ can also lead to GEFS [191] or benign familial neonatal–infantile seizures [192], while nonsense mutations are correlated with intractable epilepsy such as SMEI [193]. Voltage-gated Na^+ channel mutations may also predispose individuals to autism [194].

14.3.7 Pharmacology

Several classes of toxins and small organic compounds bind to distinct sites on voltage-gated Na^+ channels, affecting channel permeation or inactivation. The first identified toxins that could specifically block Na^+ channels are TTX and saxitoxin (STX), which have varying affinities for different members of the voltage-gated Na^+ channel family. TTX is concentrated from marine bacteria by the *Fugu* puffer fish, while STX is a poison from dinoflagellates, which are ingested by various shellfish. Both bind with low nanomolar affinity to the skeletal muscle and brain channels and have much lower affinity for the cardiac and peripheral Na^+ channels $\text{Na}_v1.8$ and 1.9. The TTX/STX binding site is determined by residues in the selectivity filter of the

channel, as well as the β subunit, and not surprisingly, these toxins block the channel pore. Both toxins contain a positively charged guanidinium group that interacts with glutamate and aspartate residues in the SS2 regions. The μ -conotoxins are peptide toxins from the *Conus* marine snails and have a guanidinium group from an arginine residue that mediates binding to the same part of the channel as TTX and STX.

A second class of toxins is composed of lipid-soluble compounds such as the plant-derived aconitine, batrachotoxin (BTX), and grayanotoxin (GTX) and veratridine, which is secreted by the skin of poisonous frogs from the *Phyllobates* genus. Unlike TTX, STX, and μ -conotoxins, these lipid-soluble toxins are activators of Na^+ channels that shift voltage activation to more negative potentials and inhibit fast inactivation. Ciguatoxins (CTX) and brevetoxin (PbTx), both derived from marine dinoflagellates, make up another class of lipid-soluble toxins that activate voltage gated Na^+ channels by shifting the voltage dependence of activation to more hyperpolarized potentials and by inhibiting fast inactivation. The type I sea anemone toxin, scorpion α -toxins, and Australian funnel-web spider-derived atracotoxins prevent fast inactivation of voltage-gated Na^+ channels by binding extracellular S3–S4 and S5–S6 linkers [195]. The peptide scorpion β -toxins bind to the extracellular end of S4 D_{II} and the S3–S4 D_{II} loop and likely stabilize the open conformation of the voltage-sensing S4 transmembrane domain [196].

Other activators of voltage-gated Na^+ channels include the pyrethroid insecticides, such as dichlorodiphenyltrichloroethane (DDT). Antiepileptic drugs like phenytoin, lamotrigine, and carbamazepine are blockers of voltage-gated Na^+ channels, and the Na^+ channel-blocking action of antidepressants such as imipramine, amitriptyline, and maprotiline may mediate sedative and arrhythmogenic side effects of these drugs. Antiarrhythmic drugs of class 1b, such as mexiletine, as well as local anesthetics have been useful treatments for paramyotonia congenita and potassium-aggravated myotonia and can be neuroprotective in some cases. Antiarrhythmic drugs have not been as useful as one might hope, however, on account of their side effects: Their tendency to promote arrhythmias in many patients is of particular concern.

Local anesthetics make up a class of voltage-gated Na^+ channel blockers that act on nociceptive fibers of the peripheral nervous system. These compounds are lipid soluble and include lidocaine, bupivacaine, benzocaine and many other compounds. They cross the membrane in order to reach their site of action at the cytoplasmic mouth of the channel, where they display use-dependent block: That is, successive depolarizations increase access of local anesthetics to their binding site on the channel [197]. Unlike the blockers TTX and STX, there is relatively little variability in local anesthetic affinity among the members of the voltage-gated Na^+ channel family. Affinities do not necessarily correlate with analgesic efficacy, since repetitive firing, not current amplitude, is what underlies nociceptive transmission [198].

14.4 VOLTAGE-GATED CALCIUM CHANNELS

Voltage-gated Ca^{2+} channels are essential for mediating cellular responses to electrical activity, exemplified by the fundamental requirement of these channels in neurotransmitter release and muscle contraction. Intracellular calcium ion concentration is highly regulated and normally maintained around 100 nM, as prolonged elevation of calcium levels can trigger cell death. Voltage-gated Ca^{2+} channels play a major role in

controlling intracellular calcium concentrations. The influx of calcium into a cell induced by the opening of a voltage-gated Ca^{2+} channel can cause over 1000-fold increase in localized calcium concentration, resulting in profound changes in cellular function.

Over the decades, an impressive body of work has examined the physiological impact of calcium currents and the proteins involved in shaping these currents. The initial cloning of a voltage-gated Ca^{2+} channel as well as the biochemical isolation of an α subunit with its auxiliary subunits occurred in 1987 [199, 200]. Over the years, a total of 10 pore-forming α_1 subunits from humans have been cloned along with a wide array of auxiliary subunits: four $\alpha_2\delta$, four β , and eight γ subunits.

Like voltage-gated sodium channels, the voltage-gated Ca^{2+} channel's pore-forming α -subunit gene encodes a 24-TM protein divided into four 6-TMS pseudorepeating domains. This pore-forming α_1 subunit interacts noncovalently with the auxiliary subunits $\alpha_2\delta$, β , and sometimes γ at nonoverlapping domains of the α_1 subunit to form a voltage-gated Ca^{2+} channel complex (Fig. 14.1b).

The interactions of these subunits can have a profound impact on the function, localization, and stability of the Ca^{2+} channel. Ultrastructural studies using electron microscopy and single-particle analysis of the skeletal muscle Ca^{2+} channel ($\text{Ca}_v1.1$, $\alpha_2\delta_1$, β_{1a} , γ_1) and cardiac Ca^{2+} channel ($\text{Ca}_v1.2$, $\alpha_2\delta_1$, β_2 , or β_3) at nanometer resolution have provided some insight into the physical association of the voltage-gated Ca^{2+} channel subunits, corroborating information gleaned from biochemical studies over the past few years [201]. High-resolution crystal structures of Ca^{2+} channel components are an enticing but challenging goal that has not been fully realized. Obtaining a more structurally refined image of the Ca^{2+} channel will provide greater insight into the channel's mechanics and function and be a guide for the development of drugs to alter Ca^{2+} channel activity.

Recently, the first crystal structures of a voltage-gated Ca^{2+} channel domain were published, depicting the 18-amino-acid stretch of the cytoplasmic domain I–II linker site where the β subunits interact with the α_1 subunit, known as the α_1 interaction domain (AID) bound to different β subunits at high resolution [202–204]. These structures reveal that the AID is an amphipathic helix. The highly conserved hydrophobic residues of the AID form a complement to the hydrophobic groove of the β subunit that is most intimate with the AID. Unlike the β subunit, it is not clear where $\alpha_2\delta$ or γ interacts with the $\text{Ca}_v \alpha_1$ subunit.

There is great diversity among voltage-gated Ca^{2+} channels. From the sheer number of possible subunit combinations that assemble to form a functional channel to the range of signaling pathways involved in these channels, great challenges and opportunities exist in pharmacologically controlling these channels. Buoyed by the early success of blocking voltage-gated Ca^{2+} channels to treat hypertension, continued efforts are underway to better understand specific roles of voltage-gated Ca^{2+} channels and to develop new and better pharmacological tools.

14.4.1 α Subunit

The broadest classifications among the 10 cloned α subunits are the high-voltage activated (HVA) and the low-voltage activated (LVA) classes of subunits [205]. The HVA Ca^{2+} channels require a large depolarization to open in normal physiological conditions. Further classification of HVA channels is now possible based upon their pharmacological profile: dihydropyridine (DHP)-sensitive channels (L type,

Ca_v1.1–1.4), ω -agatoxin IVA-sensitive channels (P and Q type, Ca_v2.1), ω -conotoxin GVIA-sensitive channels (N type, Ca_v2.2), and SNX482-sensitive channels (R type, Ca_v2.3) [8]. The remaining three cloned Ca²⁺ channels are the LVA-type channels (Ca_v3.1–3.3), also known as T-type channels, and have no known specific blockers at this time (Fig. 14.2b). These channels open at membrane potentials close to rest and have a small single-channel conductance [206, 207] but can collectively influence the excitability and signaling properties of a neuron.

Voltage-gated Ca²⁺ channels are able to selectively allow calcium entry through the cell membrane and exclude the passage of other ions, including sodium, which is roughly the same size as a calcium ion. A ring of four glutamates, one from the pore lining P loop of each pseudorepeat, is the crucial site for calcium selectivity and is conserved among all of the HVA α subunits [208]. The acidic side chains of this EEEE ring motif are believed to project into the pore interior of the Ca²⁺ channel, allowing the negatively charged carboxylate oxygens to coordinate a calcium ion. Even a subtle mutation of a single glutamate to aspartate or glutamine reduces the calcium affinity of the voltage-gated Ca²⁺ channel [209]. LVA Ca_v3 channels have a similar selectivity ring, but with two glutamates and two aspartates instead of four glutamates forming the ring.

There is a proposed hinged-lid model for the fast inactivation of voltage-gated Ca²⁺ channels [210]. S6 of D_{I-IV} acts as a docking site for the D_{I-II} linker region to block the conduction of calcium reminiscent of the ball-and-chain model seen in sodium and potassium voltage-gated channels.

14.4.2 β Subunits

Of the four known cytosolic β subunits, β_{1a} was the first discovered when it was copurified with the initial isolation of Ca_v1.1 in skeletal muscle [211]. Over the years, characterizations of the four β subunits have revealed numerous splice variants with distinct properties [212]. β_{1b} and β_{2a} , for example, have the ability to independently associate with the plasma membrane via acidic motifs or palmitoylation [213, 214].

Sequence analysis and the recent crystal structures of β_2 , β_3 , and β_4 show that β subunits are part of the membrane-associated guanylate kinase (MAGUK) family [215]. SH3, a protein–protein binding motif, and a guanylate kinase motif are the two main motifs of MAGUK proteins, although the enzymatic capability of the guanylate kinase has been modified in β subunits and is now involved in establishing protein–protein interfaces that modulate Ca_v α_1 Ca²⁺ channel function.

The ability of β subunits to physically interact with the AID was thought to be primarily mediated by a 41-amino-acid region of the β subunit known as the β -interacting domain [216]. However, crystal structures of the AID bound to a β subunit have revealed a more accurate portrayal of this region that binds to the AID, dubbed the AID binding pocket (ABP). The ABP is located at the ATP coordination site of the GK domain, but a conserved tryptophan in the AID allows the β subunit to bind to the α subunit instead of ATP.

The β subunits have a number of profound effects on the trafficking, kinetics, and voltage properties of the voltage-gated Ca²⁺ channel [217]. With the exception of some truncated splice variants, β subunits increase the functional expression of HVA Ca²⁺ channels. Almost all voltage-gated Ca²⁺ channel α subunits have an ER

retention signal located in the I–II cytoplasmic loop and β subunits shield this signal to promote exit from the ER and surface expression of the channel [218]. The β subunits also influence Ca^{2+} channels at the plasma membrane and are capable of increasing the mean open time of Ca^{2+} channels as well as shifting the voltage dependence of HVA Ca^{2+} channel activation, making the Ca^{2+} channel more apt to open when a cell depolarizes. The voltage dependence of steady-state inactivation is also shifted to more hyperpolarized potentials by β subunits, with the exception of N-terminal palmitoylated β_{2a} . Palmitoylated β_{2a} retards the inactivation of $\text{Ca}_v1.2$, 2.2, and 2.3.

14.4.3 $\alpha_2\delta$ Subunits

There are four known mammalian $\alpha_2\delta$ subunits that interact with voltage-gated Ca^{2+} channel α subunits. Expanding on this molecular diversity, at least five splice variants of $\alpha_2\delta_1$ ($\alpha_2\delta_{1a}$ to $\alpha_2\delta_{1e}$) and three of $\alpha_2\delta_2$ ($\alpha_2\delta_{2a}$, $\alpha_2\gamma_{2b}$, and $\alpha_2\delta_{2c}$) have been detected with a tissue-specific distribution pattern. A salient feature of the $\alpha_2\delta$ subunit is that it is proteolytically cleaved and the resulting α_2 and δ peptides are linked together via disulfide bridges. The entire α_2 subunit is located extracellularly and the δ subunit is a single-TM protein that acts as its anchor [219].

The α_2 subunit is heavily glycosylated and presumably this glycosylation ultimately influences the trafficking and stability of the voltage-gated Ca^{2+} channel. Indeed, $\alpha_2\delta$ generally increases the surface expression level of voltage-gated Ca^{2+} channels [220]. Depending on the $\text{Ca}_v \alpha_1$ and β subunits coexpressed with $\alpha_2\delta$ in a heterologous expression system, $\alpha_2\delta$ is also capable of accelerating both the activation and inactivation of calcium current. Like the β subunit, $\alpha_2\delta$ also shifts the voltage dependence of the Ca^{2+} channels to more hyperpolarized potentials. It is not clear how $\alpha_2\delta$ modulates these biophysical properties of the voltage-gated Ca^{2+} channel.

14.4.4 γ Subunits

The primary focus of research on γ subunits involved in Ca^{2+} channel function has been on its role in skeletal muscle, the only tissue known to express calcium γ subunits until recently. Since the discovery that the spontaneous mutation in the *stargazer* mouse line is a neuronal γ subunit [221], the number of γ subunits cloned has expanded to eight, and a number of these are expressed in the brain [222].

The γ subunits have four TM domains with intracellular amino and carboxyl termini. Features of some of the neuronal γ subunits are a cyclic adenosine monophosphate/cyclic guanosine monophosphate (cAMP/cGMP) phosphorylation consensus site and potential sites for N-linked glycosylation. The γ subunits are unique among the auxiliary subunits in not having a known influence on voltage-gated Ca^{2+} channel surface density. They also do not interfere with the $\alpha_2\delta$ or β subunits interactions with the $\text{Ca}_v \alpha$ subunit. The impact of γ subunits on voltage-gated Ca^{2+} channel electrophysiology has not been robust or clearly understood. The general consensus is that γ subunits lower the current of Ca^{2+} channels by causing a hyperpolarizing shift in the voltage dependence of inactivation.

14.4.5 Function and Pharmacology

Voltage-gated Ca^{2+} channels are expressed in all excitable cells and play numerous functional roles in a variety of signaling pathways that encode electrical activity into cellular events [4]. Although voltage-gated Ca^{2+} channels share fundamental physiological properties, the different $\text{Ca}_v \alpha$ and auxiliary subunits have specialized distributions, functions, and pharmacological sensitivities. For decades, Ca^{2+} channels have been manipulated by researchers using multivalent cations and small organic molecules. The repertoire of pharmacological manipulations has more recently been expanded using peptides mainly derived from the venoms of predatory creatures. There continue to be focused efforts on the discovery and synthesis of new compounds to influence voltage-gated Ca^{2+} channel behavior [223].

14.4.5.1 General Blockers. Certain metal ions are capable of nonselectively blocking voltage-gated Ca^{2+} channels. Cadmium ions block all HVA Ca^{2+} channels. Nickel ions were historically used to block LVA channels, but only $\text{Ca}_v3.2$ of the LVA family as well as a number of HVA channels are actually blocked by nickel [224]. Trivalent cations such as lanthanum, yttrium, and holmium are potent blockers of all voltage-gated Ca^{2+} channels. These multivalent ions block voltage-gated Ca^{2+} channels primarily by occlusion of the α_1 pore region containing the EEEE ring of glutamic acid residues. These ions also have secondary effects outside of the pore region that influence the biophysical properties of voltage-gated Ca^{2+} channel.

14.4.5.2 Ca_v1 Family. $\text{Ca}_v1.1$ expressed in skeletal muscle is directly coupled with ryanodine receptors that line the sarcoplasmic reticulum, which stores intracellular calcium. Depolarization of skeletal muscle plasma membrane opens $\text{Ca}_v1.1$ with slow kinetics, causing activation of ryanodine receptors and leading to intracellular release of calcium. The released calcium from the internal stores binds to proteins such as troponin and ultimately allows myosin to generate the force necessary for contraction. Mutations of $\text{Ca}_v1.1$ have been associated with malignant hyperthermia, a condition in which a normally healthy individual can experience a life-threatening release of calcium from the sarcoplasmic reticulum when given anesthetics or muscle relaxants [225]. The mutation is a substitution of an arginine to histidine or cysteine in the cytoplasmic III–IV linker that appears to lower the depolarization threshold needed to induce the ryanodine receptor to release calcium from the sarcoplasmic reticulum stores [226].

The Ca_v1 family is important in cardiac and smooth muscle function. $\text{Ca}_v1.2$ and $\text{Ca}_v1.3$ are involved in pacemaking activity for the heart by controlling rhythmic entry of calcium in the sinoatrial and atrioventricular nodes. They also have roles in neurons along with the classical neuronal Ca_v2 family in regulating synaptic activity and gene expression. Unlike the predominantly axonal distribution of Ca_v2 channels, $\text{Ca}_v1.2$ – 1.4 have a more somatodendritic distribution in neurons. Ca_v1 channels possess a binding site for calmodulin, a calcium binding protein that can activate many signaling pathways in a calcium-dependent manner. Synaptic activity that leads to Ca_v1 channel opening can initiate nuclear signaling and activation of transcription factors such as cAMP response element binding (CREB) protein, leading to changes in gene transcription. Ca_v1 channels are able to both recruit and

activate calmodulin by providing a calmodulin binding site as well as a calcium ion source from the open channel. Calcium-bound calmodulin is capable of activating a number of kinase pathways, including ones that phosphorylate CREB, encouraging its nuclear entry and activity as a regulator of transcription [227].

$\text{Ca}_v1.4$, the most recently cloned of the Ca_v1 family, is the least understood, but a channelopathy, incomplete congenital stationary night blindness (CSNB2), caused by mutations in $\text{Ca}_v1.4$ has illuminated one of the roles of this channel. CSNB2 presents itself with a combination of symptoms such as myopia, nystagmus, reduced visual acuity, or night blindness. Over 40 mutations in $\text{Ca}_v1.4$, ranging from amino acid substitutions to truncations, have been identified in CSNB2 patients [228]. It is not clear how these particular mutations of $\text{Ca}_v1.4$ compromise channel function. $\text{Ca}_v1.4$ is ideally suited for controlling tonic neurotransmitter release because it has a rather low threshold for activation at around -40 mV and inactivates slowly. Moreover, $\text{Ca}_v1.4$ is expressed in the retina, and electroretinograms of CSNB2 patients indicate a defect in the tonic neurotransmission that occurs between photoreceptors and second-order neurons [229].

The most varied and clinically useful Ca^{2+} channel pharmacological agents are those that block Ca_v1 channels to treat hypertension, angina, and certain arrhythmias [230]. The actions of dihydropyridines on Ca_v1 channels have been studied since the 1980s and their influences on the channel are complex. The ability of dihydropyridines to interact with Ca_v1 channels is state dependent; dihydropyridines are inferior blockers when Ca_v1 Ca^{2+} channels are closed during hyperpolarizing conditions. There is also evidence that dihydropyridines promote the Ca^{2+} channel to be in an inactive state, reducing the channel's current [231]. The sites of dihydropyridine interaction with Ca_v1 have been isolated using mutagenesis studies, and a key conserved site is a threonine in S5 of domain III in $\text{Ca}_v1.2$ [232]. Moreover, a number of sites in domains III and IV also contribute to Ca_v1 's dihydropyridine sensitivity [233, 234].

Like cardiac and skeletal muscle, vascular smooth muscle utilizes voltage-gated Ca^{2+} channels for regulating intracellular calcium levels that are responsible for muscular contraction. Using the dihydropyridine group of drugs has been clinically useful to treat hypertension by blocking Ca_v1 [235]. Reducing Ca_v1 channel activity reduces calcium entry into vascular smooth muscle and consequently reduces vascular pressure.

14.4.5.3 Ca_v2 Family. The members of the Ca_v2 family are expressed in a range of organs such as the pancreas, heart, and testis. However, their widespread presence in the central nervous system and their importance in neuronal function have been the overriding focus of Ca_v2 channel studies. The three Ca_v2 channel types have different pharmacological sensitivity profiles and specialized roles, but a common trait among them is their regulation of neurotransmitter release. Located at the presynaptic end of an axon, Ca_v2 channels open and allow calcium to enter the axonal terminal when an action potential pulse reaches the end of its path along an axon. Calcium ions that enter through Ca^{2+} channels and the channels themselves are key players in second-messenger pathways leading to presynaptic release of neurotransmitters [236]. $\text{Ca}_v2.1$ and $\text{Ca}_v2.2$ contain a synaptic protein interaction motif in the II–III intracellular loop that binds with various proteins that are part of the neurotransmitter release machinery such as synaptotagmin I, syntaxin I, and SNAP-25 [237]. This

voltage-gated Ca^{2+} channel involvement in linking electrical activity with exocytic release is also utilized in other physiological contexts such as hormone release [238].

Unlike the Ca_v1 family, individual Ca_v2 α subunits have specific blockers. The best known pharmacological modulators of the Ca_v2 family are peptides derived from the venom of predatory animals. Comprised of 20–30 amino acids, these peptides can be rather specific, capable of binding to a particular Ca_v2 subunit at nanomolar concentrations.

The most specific blocker of $\text{Ca}_v2.1$ is the 48-amino-acid ω -agatoxin isolated from the American funnel spider *Agelenopsis aperta*. However, it also blocks $\text{Ca}_v2.2$ with low affinity, as well as $\text{Ca}_v2.3$. Blockade by ω -agatoxin is irreversible and likely interferes with the $\text{Ca}_v2.1$ voltage sensor. The S3–S4 region of DIV is the major site where ω -agatoxin interacts with $\text{Ca}_v2.1$ [239]. The P- and Q-type calcium currents arise from different splice variants of $\text{Ca}_v2.1$. The Q-type $\text{Ca}_v2.1$ splice variant has an addition of an asparagine and proline in the agatoxin interaction region, resulting in a lower agatoxin binding affinity.

The venom from the sea snail *Conus geographus* contains a 27-amino-acid peptide ω -conotoxin GVIA that is a selective, irreversible blocker of $\text{Ca}_v2.2$ N-type channels. ω -Conotoxin GVIA blocks $\text{Ca}_v2.2$ by physically occluding the pore [240]. Other selective N-type blocking peptides are ω -conotoxin MVIIA and MVIIIC from the *Conus magus* snail and the ω -conotoxin CVID isolated from *Conus catus*.

The therapeutic and commercial success of Ca_v1 channel blockers has inspired the possibility that specific Ca_v2 channel blockers have therapeutic potential as well. The most promising application is to use the Ca_v2 channel blockers for pain treatment. The impetus for finding pharmacological modulators of Ca_v2 channels is that the channels are highly expressed in the superficial layer of the dorsal horn of the spinal cord, an area where nociceptive signaling is transmitted. It is hoped that blocking Ca_v2 channels will block mediators of nociceptive signaling such as substance P [241]. The promise of this strategy is supported by $\text{Ca}_v2.2$ knockout mice having lowered sensitivity to neuropathic and inflammatory pain, and current μ -opioid receptor agonists used for pain relief, such as morphine, partially block Ca_v2 channels [242, 243]. Ziconotide, a compound derived from ω -conotoxin MVIIA, has been approved for clinical use by the Food and Drug Administration (FDA) and the European Commission for treating severe chronic pain. Currently, ziconotide can only be administered intrathecally and there are some cases of severe side effects such as unruly behavior and hypotension [244]. More toxin-derived Ca_v2 channel blockers are in various stages of development for pain treatment [245]. In addition, small organic molecules that specifically target Ca_v2 have the advantage of being orally administered and are also being developed and reviewed for pain treatment [246].

Until recently, there were no known pharmacologic blockers of $\text{Ca}_v2.3$ Ca^{2+} channels, but it is now known that these channels are blocked by SNX-482, a compound isolated from the venom of the tarantula *Hysteroecrates gigas* [247]. SNX-482 also partially inhibits Ca_v1 channels with low affinity, but SNX-482 is the best $\text{Ca}_v2.3$ blocker to date [248].

14.4.5.4 Ca_v3 Family. The Ca_v3 family is the least understood among the voltage-gated channels, but its members are known to be expressed in many tissues. Opening

at potentials near the resting membrane potential, Ca_v3 channels can influence the membrane potential of the cell at rest. There is also evidence that Ca_v3 channels affect rhythmic neuronal firing.

Despite years of intense effort, there are still no specific and effective pharmacological blockers of Ca_v3 channels. As a result, studies of Ca_v3 have been hindered, but there is growing evidence for functional roles of Ca_v3 channels and the potential benefits of developing specific Ca_v3 pharmacological targets.

Like $\text{Ca}_v2.2$, $\text{Ca}_v3.2$ and $\text{Ca}_v3.3$ are expressed in the dorsal root ganglion neurons of the superficial lamina. Given Ca_v3 's low activation threshold kinetics, blocking these channels can reduce the overall excitability of a neuron. A number of pain models suggest that an increase in excitability of nociceptive neurons contributes to pain perception. Blocking Ca_v3 neurons could hamper these neurons' excitability and subsequently suppress nociceptive signaling [245].

14.4.5.5 Auxiliary Subunit Modulators. Given the substantial functional modifications that auxiliary subunits can have on voltage-gated Ca^{2+} channel properties, drugs that bind to these Ca^{2+} channel auxiliary subunits may also lead to alterations in Ca^{2+} channel function. One such example is the anticonvulsant drug gabapentin. Gabapentin interacts with a number of proteins, including $\alpha_2\delta_1$ [249]. Both the α_2 and δ subunits are required for gabapentin binding, but it is not known how this binding alters voltage-gated Ca^{2+} channel function. The general effect of gabapentin on voltage-gated Ca^{2+} channels is a reduction in macroscopic current. Besides the anticonvulsant properties of gabapentin, it has also been found to relieve neuropathic pain. Gabapentin's analgesic properties may be attributable to its block of $\text{Ca}_v2.2$ current in the dorsal root ganglia.

14.5 OTHER VOLTAGE-GATED CHANNELS

The superfamily of voltage-gated cation channels contains several other important channel types, including the cyclic nucleotide-gated (CNG) channels, the hyperpolarization-activated channels (HCN), and the transient receptor potential (TRP) channels. CNG channels are nonselective cation channels and are crucial for the receptor-mediated transduction of visual and olfactory information through cyclic nucleotide second-messenger pathways [250]. HCN channels are nonselective, gated by cyclic nucleotides, and are opened at voltages hyperpolarized to the resting potential. They play a role in pacemaker activity of neurons and of the heart [251]. TRP channels are nonselective and only weakly voltage sensitive. They are more distantly related to Kv channels than the HCN or CNG families. These channels play a role in a variety of sensory systems, including nociception, thermosensation, and taste sensation [252].

Other unrelated classes of voltage-gated ion channels include voltage-gated proton channels and voltage-gated chloride channels. The voltage-gated proton channel is an essential part of the oxidative burst of phagocytic cells of the immune system, providing a cationic shunt for the large, anionic superoxide flux generated by the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase [253]. This channel has not yet been cloned. Voltage-gated chloride channels, or ClC channels, are a subset of anion channels that is entirely

unrelated structurally to cation channels. These channels modulate muscle cell excitability, endosomal and vesicular acidification, epithelial transport, bone resorption, and cell swelling [254].

15.1 NEUROPEPTIDE CONCEPT

The neuroendocrine system integrates the regulatory functions of the nervous and endocrine systems, involving the neurosecretions of hypothalamic neurons controlling the activity of the anterior pituitary gland. These interactions are notable for the elaborate systems of feedback controls, chiefly negative. Since the late 1960s and early 1970s, when it was shown that the pituitary and hypothalamic hormones are peptides, that the endorphins and enkephalins are peptides, and that the gut peptides—such as cholecystokinin (CCK), vasoactive intestinal polypeptide (VIP), and somatostatin—are also produced in the brain, interest and investigation into the actions of peptides have grown exponentially.

What makes a peptide a neuropeptide? The demonstration that brain peptides have direct effects on neurons involved in behavior was first shown by De Wied [1] and Kastin et al. [2]. The dissociation of the endocrine and neural effects of adrenocorticotrophic hormone (ACTH) using fragments devoid of adrenocorticotrophic action [3–6] led to the *neuropeptide concept*: that peptides produced in the brain

and gut have direct effect on central and peripheral neurons. This novel idea took many years to be accepted [7]. Today we are aware that neuropeptides affect nonneural tissues and organs as well as neurons and they integrate almost every system of the body: reproduction; growth; water and salt metabolism; temperature control; food and water intake; cardiovascular, respiratory, and gastrointestinal control; and affective states. When we add to this list their participation in autonomic responses, nerve development, and regeneration and their increasing involvement with food intake and body weight regulation [8], their importance becomes self-evident.

New and ever more sophisticated methodologies have enabled the better understanding of the actions, relationships, and regulatory actions of these molecules. The number of neuropeptides identified grows almost daily, and peptides with neurogenic activities have been isolated from many nonendocrine sources. They are found in the brain and spinal cord, sensory neurons of the spinal ganglia that contain substance P (SP), somatostatin (ST), VIP, and CCK, among other neuropeptides, and almost all peripheral organs where they may act as autocrine, paracrine, or endocrine factors. They are present in sources as disparate as frog skin, shark mouth, the invertebrates, and plants, most of which affect mammalian tissues as well as their host tissues. Table 15.1 indicates the source of some of the most important neuropeptides.

The coexistence of neuropeptides with the classical neurotransmitters, such as norepinephrine and acetylcholine or γ -aminobutyric acid (GABA), extends the dispersion of many neuropeptides to central, peripheral, and autonomic nerve terminals, and the presence of two or more neuropeptides in the same nerve terminal indicates the complexity of their possible synergistic/antagonistic actions. Neuropeptides have been reported to coexist with transduction molecules, suggesting that peptides are not randomly expressed with regard to their signal transduction molecules.

Topics to be discussed in this chapter will include the identification and processing of neuropeptides, the evolution of neuropeptide families together with the evolution of their complex receptor subtypes, the importance of time-sensitive responses to neuropeptides, especially in development and regeneration, and the apparent redundancy of many neuropeptides as evidenced by “knockout” animals. Information derived from new methodologies such as genomics and proteomics brings our understanding of neuropeptides to a genomic and even molecular level.

15.2 IDENTIFICATION OF NEUROPEPTIDES

In this section we discuss some of the techniques used to identify neuropeptides:

1. *Bioassay* This is the earliest technique for the functional identification of a hormone. It determines the effect of administration of that hormone to an animal from which the endogenous source of that hormone has been removed. Removal of the thyroid gland results in severe metabolic disturbances that can be returned to normal through the administration of thyroxine (T_4). The concentration of a hormone in tissue, plasma, or urine can also be quantified, but most in vivo bioassays are not sensitive enough to measure normal or below-normal levels of the hormone.

TABLE 15.1 Mammalian Neuropeptides Classified According to Principle Sources and Other Sources

Principal Sources	Other Sources
Hypothalamic Peptides	
Agouti-related protein	
β -Endorphin	
CART ^a	Pituitary, striatum, adrenal medulla
Corticotropin-releasing hormone	Pituitary, median eminence, brain, spinal cord
Galanin	Locus ceruleus
Gonadotropin-releasing hormone	Placenta, gonads?
Growth hormone-releasing hormone	Placenta
Melanin-concentrating hormone	
Orexin/hypocretin	
Oxytocin ^b	Posterior pituitary, brain, spinal cord
Pituitary adenylate cyclase-activating polypeptide	Thalamus, hippocampus, spinal cord
Proopiomelanocortin	Pituitary
Somatostatin	Brain, spinal cord, gut, salivary glands, excretory system
Thyrotropin-releasing hormone	Brain, spinal cord, gut, pancreas
Tyr-MIF-1	Cerebral cortex
Vasopressin ^b	Posterior pituitary, brain, spinal cord, peripheral nerves
Anterior Pituitary Peptides	
Adrenocorticotropin	Median eminence, brain, spinal cord, placenta, gut, lymphocytes
β -Endorphin	Median eminence, placenta, gut
Follicle-stimulating hormone	Median eminence, placenta
Growth hormone	Median eminence, placenta
Luteinizing hormone	Median eminence, placenta
Melanocyte-stimulating hormone	Median eminence, brain, spinal cord, peripheral nerves
Prolactin	Median eminence, brain, spinal cord, placenta
Thyroid-stimulating hormone	Median eminence, placenta
Brain and Spinal Cord Peptides	
δ Sleep-inducing peptide	
Dynorphins	
Endorphins	Pituitary
Met- and Leu-enkephalin	Myenteric neurons, peripheral nerves
Neuropeptide glutamine (<i>E</i>)isoleucine-(1)	
Neurotensin	Cardiovascular system, gastrointestinal tract
Nociceptin/orphanin	Brain stem, trigeminal ganglion, central nervous system?
Secretoneurin	

TABLE 15.1 (Continued)

Principal Sources	Other Sources
Major Gut and Pancreatic Peptides	
Ghrelin	Stomach, intestine, placenta, pituitary, hypothalamus?
Calcitonin gene-related peptide, gastrointestinal tract	Brain, spinal cord, neuromuscular junctions, thyroid
Cholecystokinin, intestine	Brain, pituitary, adrenal medulla, peripheral nerves
Galanin, intestine	Brain, spinal cord, almost all peripheral systems and organs
Gastrin, gastric antrum	Pituitary, spermatozoa

^aCocaine- and amphetamine-regulated transcript.

^bProduced in hypothalamus but stored in neurohypophysis and called neurohypophyseal peptides.

2. *Cytochemical Assay* This technique, developed by Chayen and Bitensky [10], is a more sensitive technique than the bioassay and is based on the development of a colored precipitate formed as a result of a hormone-dependent intracellular reaction. The precipitate is analyzed by microspectrometry and microdensitometry.
3. *Radioimmunoassay (RIA)* The RIA was developed by Berson and Yalow in 1960 and is less sensitive than the cytochemical assay, but it is less demanding. It can measure femtomoles of neuropeptides and is the most convenient and accurate method of determining neuropeptide concentrations, especially in characterizing the rhythms of the release of many of the hypothalamic and pituitary hormones.
4. *Immunocytochemistry* This technique permits the anatomical localization of neuropeptides through their immunoreactivity as detected by specific antisera. Classically this method has demonstrated the pathways of monoamines in the central nervous system (CNS) [11]. A major disadvantage of this technique is that the antibodies may recognize biologically inactive parts of the peptide or bind to the degraded portion of the peptide. Consequently, it is usual to refer to the reactivity as “-like,” as in growth hormone-like immunoreactivity.
5. *Immediate Early Genes* These are expressed early and transiently (within an hour) in active tissues, permitting the location of cellular activity through immunocytochemical techniques that locate the immediate early genes. The best studied immediate early genes are *c-fos* and *c-jun*. When this technique is combined with pathway-tracing methods, it provides a powerful tool for defining active neuropeptide pathways [12].
6. *Autoradiography* This consists of the administration of a radioactive neuropeptide and the subsequent incubation of tissue slices or cell cultures to permit the visualization of the binding site. Other labeling techniques are used, such as labeling with colloidal gold and subsequent identification through electron

microscopy [13, 14]. *Neuropeptide receptors* can be selectively labeled and visualized microscopically on autoradiograms (microscopic receptor mapping). In vivo receptor mapping has several drawbacks [15]. In vitro visualization of receptors is much more sensitive as the visualization is amplified through image-intensified fluorescence microscopy and fluorophores, the most commonly used being fluorescein and rhodamine derivatives [16].

7. *In Situ Hybridization and Histochemistry* This is used more often because the visualization of the receptor messenger RNAs (mRNAs) permits the identification of the cells that synthesize the receptors. The development of highly selective agonists and antagonists, together with quantitative receptor autoradiography in vivo and in vitro, has revealed complex pharmacological responses and specific receptor subtypes [17]. *Histochemistry* is used to study the regulation of selected mRNA species in single neurons and is based on the ability of radiolabeled DNA that is complementary to a specific mRNA to bind to specific mRNA in tissue sections. Either an oligonucleotide or an RNA probe is usually selected. Immunohistochemistry is usually performed before in situ hybridization to localize both the hybridization signal and an immunohistochemical label within the same cell [18].

Other techniques that measure neuropeptide release include in vivo sampling and microdialysis, antibody microprobes, in vivo perfusion methods, reversed-phase high-performance liquid chromatography (HPCL) [19], and the cell blot assay [20].

15.3 ISOLATION AND CHARACTERIZATION OF NEUROPEPTIDES

Many methods have been used for the isolation and characterization of neuropeptides, including biological and chemical assays, peptide purification, peptide and nucleotide determination, and molecular biotechnology. Peptides isolated on the basis of one biological function often have many other functions. Peptides isolated on the basis of their chemical characteristics frequently have no known biological function, because biological activity often depends on posttranslational modifications. Many synthetic neuropeptides, manufactured on the basis of their amino acid sequence in the precursor hormone, may have potent biological effects yet cannot be demonstrated in physiological systems. However, some synthetic analogs have more powerful and longer lasting effects than the endogenous neuropeptide, an outcome of considerable clinical significance.

Peptides can be separated by chromatography and capillary electrophoresis and detection and by absorbance, fluorescence, electrochemistry, and immunoassay techniques [21]. Some frequently used methods of peptide isolation and structure analysis include fast atom bombardment spectrometry [22], size exclusion HPLC linked to electrospray ionization mass spectrometry [23], and matrix-assisted laser desorption ionization time-of-flight mass spectrometry [24]. These techniques, when combined with two-step liquid chromatography, provide another rapid and reliable method for the identification of bioactive molecules, as recently described for five new bradykinin-potentiating peptides [25].

15.4 PEPTIDOMICS

The term peptidomics refers to techniques that permit the quantitative determination of the peptide content of whole cells. New peptides are being discovered using single-cell mass spectrometry, which permits the measurement of molecular weights of peptides and proteins from single-cell samples [26]. A technique that includes the virtual visualization and identification of the peptides as two- and three-dimensional image maps is a powerful method for investigating endogenous peptides and their posttranslational modifications in complex tissues such as the brain [27, 28]. Recently, an approach termed *combinatorial peptidomics* was introduced. This is based on the selective crosslinking of peptides to a bead surface specifically reactive for a peptide side chain such as sulfhydryl or hydroxy [29].

15.5 NEUROPEPTIDE RECEPTOR AGONISTS AND ANTAGONISTS

The development of peptide receptor antagonists that selectively block the action of the peptide through binding to its receptor is an invaluable tool in investigating the function of those peptides for which receptor antagonists have been developed. The opiate antagonist naloxone is a specific narcotic antagonist and has been used extensively to study the specificity of opiate action. Synthetic antagonists to SP and other members of the tachykinin family have resulted in the identification of several receptor types and subtypes, often with quite different properties.

15.6 ELECTROPHYSIOLOGICAL TECHNIQUES

Neuropeptides can modulate the ion permeability of the neuronal membrane [30]. Many neuropeptides act as neurotransmitters, neuromodulators, or both, and these functions can best be investigated by electrophysiological methods. A common technique in the CNS utilizes chronically implanted microelectrodes that record single cells in conscious animals. Neuropeptides may be administered directly onto individual cells by microiontophoresis or pressure ejection and the response of the target cell recorded. These methods have been able to distinguish whether the applied neuropeptide is acting as a neurotransmitter or neuromodulator depending on the change in membrane potential of the responding cell [31].

15.6.1 Neurohormone, Neurotransmitter, or Neuromodulator?

15.6.1.1 Neurohormone. A neurohormone is secreted into the circulation and binds to a specific receptor on the target cell membrane. This initiates a cascade of metabolic reactions, usually through G-coupled proteins and cyclic adenosine monophosphate (cAMP). *Classical neurotransmitters* such as acetylcholine (ACh) epinephrine, dopamine, and GABA are synthesized in nerve terminals and stored in small, clear vesicles. Synthesis is rapid and there is little chance of neurotransmitter depletion. In contrast, synthesis of neuropeptides is slow and they are stored in large dense-core vesicles (LDCVs) that are moved by axonal transport to nerve terminals. Neuroendocrine cells may respond to either or both electrical stimulation and

hormonal stimulation. Hormonal stimulation induces secretion in neuroendocrine cells via binding of the hormone to the membrane-bound receptor, initiating the cascade of second-messenger reactions and the release of cytosolic Ca^{2+} . *Exocytosis*, a calcium-dependent function, entails the fusion of the membrane of the LDCVs with the presynaptic membrane. Details of this process are described by Nicholls [32] and Burgoyne and Morgan [33]. The contents of the LDCVs are spilled into the extracellular space and the vesicle membranes recycled.

Neuroendocrine cells respond to an electrical stimulus through voltage-gated sodium, calcium, and potassium channels that mediate the all-or-nothing potentials associated with the rise in $[\text{Ca}^{2+}]_i$. Four major types of calcium channels have been identified, and after a rise in cytosolic free Ca^{2+} , neuroendocrine cells display a wide repertoire of electrical responses to secretagogues [34].

15.6.1.2 Neurotransmitters. Neuropeptides acting as neurotransmitters are characterized by latencies on the order of hours rather than milliseconds. Higher frequencies are usually required for a neuropeptide, secreted from a neuroendocrine cell and acting as a neurotransmitter, to evoke a response, which then is slower and longer lasting [35]. As with the classical neurotransmitters, neuropeptide release is Ca^{2+} dependent, but there is no evidence for organization of the dense-core neuropeptide-containing vesicles at the presynaptic membrane. Again, unlike the classical neurotransmitters, there does not appear to be any specific inactivating mechanism: Inactivation depends on nonspecific proteases and peptidases. SP is the typical excitatory neuropeptide transmitter, producing slow noncholinergic excitatory postsynaptic potentials (EPSPs) on spinal motor neurons and on neurons in sympathetic ganglia. Depletion of SP by capsaicin abolishes these potentials. Similar experiments with gonadotropin-releasing hormone (GnRH) showed it to be a neurotransmitter in frog sympathetic ganglia where it coexists with ACh. GnRH produces a late, slow EPSP, different from the rapid ACh-evoked potentials [36]. SP and GnRH are secreted from presynaptic nerve endings in response to Ca^{2+} influx and may either hyperpolarize or depolarize the postsynaptic membrane. A single, above-threshold impulse is sufficient to cause a response.

15.6.1.3 Neuromodulators. Neuromodulators fine tune synaptic and nonsynaptic processes by altering the effects of the classical neurotransmitters with which they coexist in nerve terminals. They act more slowly than the classical neurotransmitters and their effects are longer lasting as they affect G-protein-linked receptors and subsequent second-messenger systems. When a neuropeptide is acting as a *neuromodulator*, it also is secreted in response to Ca^{2+} influx, but it is not capable of evoking an excitatory (EPSP) or inhibitory postsynaptic potential (IPSP). Rather it facilitates an EPSP or exacerbates an IPSP evoked by a neurotransmitter. The modulatory action of thyroid-stimulating hormone (TSH) on the discharge patterns of neurons in the brain stem is clearly demonstrated by Dekin et al. [37]. Neuromodulator release is dependent upon the duration, frequency, and pattern of nerve stimulation. Neuromodulators are effective in very low concentrations (picomolar), but their biological activity may depend upon the form of the processed neuropeptide; for example, somatostatin 28, somatostatin 14, and somatostatin 12 may differ considerably in their potencies. No specific inactivating mechanisms are known.

A neuropeptide may act as a neurohormone at some sites, a neurotransmitter at others, and a neuromodulator at still other sites. For example, hypothalamic neurons release vasopressin (VP) into the posterior pituitary, where it is stored and released into the circulation as a neurohormone, whereas other nerve endings of hypothalamic neurons containing VP may terminate in various brain areas where it acts as either a neurotransmitter or a neuromodulator. In the gut and in both male and female reproductive systems vasoactive intestinal polypeptide (VIP) acts as a neurotransmitter, evoking widespread relaxant activity and increasing blood flow to the sex organs. VIP coexists with ACh in both central and peripheral cholinergic synapses where it modulates cholinergic activity by a postsynaptic mechanism. In the frog neuromuscular junction, VIP acts as a modulator but by a different mechanism: It increases the release of ACh but has no direct postsynaptic effect [38]. Similarly, SP, an excitatory neurotransmitter in spinal motoneurons, is a neuromodulator in sympathetic ganglia where it facilitates both nerve-stimulated EPSPs and the depolarization caused by local application of ACh.

Interestingly, many *insect neuropeptides* also appear to be multifunctional in that they may act as neuromodulators and/or neurohormones, regulating homeostasis, the organization of behaviors, and the initiation and coordination of development and neuromuscular activity. They lend themselves favorably to the study of neuropeptide function due to the ready availability of molecular genetics methods [39].

Neuropeptides may be *colocalized* with other neuropeptides or with the classical neurotransmitters, such as ACh, norepinephrine, dopamine, serotonin, or GABA. In some neurons, two or more neuropeptides may be present in the same secretory granule and, depending on the processing of the prohormone, lend immense flexibility to the regulation and modification of synaptic events [40].

15.7 PERFUSION AND TISSUE CULTURE STUDIES

Many different *in vitro* perfusion preparations are used, ranging from the isolated pituitary gland to chunks of tissue such as hypothalamic–neurohypophyseal explants, in which much of the neural and vascular connections can be maintained. Brain perfusion studies have identified separate and distinct transport systems of neuropeptides across the blood–brain barrier (BBB) [41]. Penetration of neuropeptides across the BBB is discussed in Section 15.18.

Fetal spinal cord slices or dissociated spinal and sensory neurons can be propagated in a liquid culture medium or in a semisolid agar medium and the effect of neuropeptides on neurite growth determined [42, 43]. A more sensitive assay uses the three-chambered tissue culture system [44, 45].

15.8 BEHAVIORAL TECHNIQUES

The pioneering studies by De Wied and his group [46, 47] and Kastin and his colleagues [48] clearly demonstrated that ACTH and its noncorticotropic peptide fragments, including melanocyte-stimulating hormone (MSH), have potent effects on adaptive behavior in rats. Behavioral tests in humans include tests of visual

discrimination, attention, and memory. Attentional and processing abilities may be enhanced by ACTH or MSH fragments [49]. There is some correlation between changes in brain peptides and Alzheimer's disease [50].

15.9 GENETIC MANIPULATIONS

15.9.1 Transgenic Animals

The generation of transgenic mice has become a powerful device for focusing on the mechanisms of gene regulation, gene promoter characteristics, enhancer sequences, and tissue-specific expression. Transgenesis applies to the introduction of new genes into mammalian organisms and the resulting animals are referred to as transgenic animals. The techniques of producing transgenic mice are described in detail by Evans et al. [51]. The overall physiological consequences of a specific, artificial mutation can be investigated in the intact animal and the effects of an over- or underproduction of a specific neuropeptide determined. This is a powerful tool for focusing on the mechanisms of gene regulation. In a mouse model that expresses a transgene that causes an overproduction of corticotropin-releasing hormone (CRH) the animals exhibit endocrine abnormalities involving the hypothalamic–pituitary–adrenal (HPA) axis and serve as a genetic model for chronic stress [52, 53].

15.9.2 Gene Targeting and Knockout Mice

An important research tool is gene targeting, a procedure in which a single gene is selected and inactivated or “knocked out.” The inactivated (null) gene is injected into early mouse embryos and replaces the normal gene in the mouse chromosome. Subsequent generations of deficient mice have an inheritable, complete loss of function in all tissues at all stages of development that were affected by the normal gene. The specific role of the knocked-out gene can then be determined by observing the physiological and structural changes resulting from the absence of the normal gene. A large number of neuropeptide genes have been tested for their ability to target expression to the hypothalamus and pituitary in transgenic mice [54]. A CRH-deficient mouse has deficiencies in stress responses, diurnal rhythms, and feeding behavior. Some of the problems involved in producing the null CRH gene are discussed by Muglia et al. [55]. Neuropeptide Y (NPY) knockout mice and mice and rats overexpressing the NPY gene indicate that the stress-related behaviors and regulation of involuntary alcohol intake are perhaps clinically the most important functions of central NPY [56]. Similarly, the physiological actions of peptides of the calcitonin family have been recently defined through gene knockout and overexpression strategies [57].

15.9.3 Genomics

Modern genetic techniques, such as genomics, are being used to probe the molecular basis of behavior in animals. A classic example is that of the prairie vole, an animal that is monogamous, and the closely related promiscuous meadow vole. This trait is governed by the neuropeptide VP and the DNA sequence for VP is the same in both

species. Similarly the sequence for the receptor gene is the same. However, the prairie voles have far more VP receptors. The difference lies in the longer regulatory region at the beginning of the receptor gene in the prairie vole. When the prairie vole's VP receptor gene, together with its regulatory region, is placed into meadow vole embryos, the resulting adult males changed their promiscuous behavior and remained faithful to their mates [58].

15.9.4 Site-Directed Mutagenesis

With the ability to create almost any desired mutation in a given DNA sequence, site-directed mutagenesis permits the introduction of a selected mutation into a specific location. This approach is invaluable for the study of neuropeptides, their precursors, and the precise sequence(s) responsible for such processes as receptor binding [59].

15.10 INTEGRATED PHYSIOLOGICAL, PEPTIDOMIC, AND GENOMIC TECHNIQUES

Many neuropeptides affect a great many physiological processes. Neuropeptide Y and galanin are two hypothalamic neuropeptides that affect a variety of physiological reactions related to nutrient and energy homeostasis. To study these interactions, endocrine, metabolic, behavioral, and neural techniques are required [60]. The complex physiological responses to the stress-evoked hormones [CRH, ACTH, VP, oxytocin (OT), endorphins, and prolactin] are interpreted through measurements of cardiac and pressor changes, alterations in reproductive endocrinology and behavior, analgesia and locomotor activity, and alterations in the immune system. How genes are regulated is of importance equal to that of gene mutations and polymorphisms in differential susceptibility to disease. Information derived from postgenomic bioinformatic and transgenic approaches, together with the mass of information available on the genetic linkage of noncoding polymorphisms, can help us understand how inappropriate regulation of neuropeptide gene expression can lead to human disease [61]. The challenge is to bring order into the mass of data and discover the pattern by which neuropeptides regulate physiological processes.

15.11 EVOLUTION OF NEUROPEPTIDES

15.11.1 Conservation of Structure

The structure of neuropeptides has been strongly conserved during evolution and must have evolved together with the necessary components of the signaling system, such as receptors, processing enzymes, and inactivation mechanisms. Once this complex integrated system had evolved in simple organisms, it probably would have remained intact in more complex animals, conserving the more active portion of the molecule. For example, the mammalian insulins are very highly conserved with only one or two sequence differences between porcine, bovine, and human insulin, suggesting that almost all the insulin structure is essential for its function. In contrast, there is little homology between porcine and rat relaxin, a peptide hormone

produced during pregnancy, indicating considerable divergence between these two species. The hypothalamic decapeptide GnRH, which stimulates the pituitary to produce the gonadotropic hormones that regulate reproduction and sexual behavior, plays a pivotal role in all vertebrates and in some invertebrates and protochordates [62–64] and therefore is highly conserved. Through gene duplication two and even three forms of GnRH have evolved [65].

Conservation of structure does not mean retention of initial function or inability to gain new functions. Prolactin (PRL), one of the oldest peptide hormones, has changed its function radically throughout evolution. In all species, from fish to humans, PRL is involved in water and salt metabolism; in birds it is vital for crop milk production; in mammalian females it is responsible for lactation; and in mammalian males, including humans, PRL is involved in spermatogenesis, testosterone synthesis, and male libido.

15.11.2 Gene Duplication and Neuropeptide Families

Neuropeptides form families of closely related peptides in which the biologically active part of the molecule is closely conserved (Table 15.2). Our understanding of the evolution of neuropeptide families is incomplete, but analyses of the amino acid sequences and the identification of the whole peptidome of a cell or tissue (peptidomics) lead to the concept that these neuropeptide families have been generated through successive events of gene and exon duplication within a common ancestral neuropeptide. This process temporarily frees one part of the genome from selective pressure and permits a small error rate of mutation. New receptors and processing enzymes probably also evolved from existing receptors through gene duplication and show familial relationships as required by their neuropeptide ligands and substrates respectively. PRL, one of the oldest of the neuropeptides, belongs to the growth hormone family, which includes the insulin-like family, the enkephalins, the gut hormones, and the tachykinins (SP, neurokinin A, neurokinin B, eladoin, and physalaemin), all of which share the amino acid sequence of SP. A fine review of the role of mutations in the evolution of vertebrate neuropeptides can be found in Holmgren and Jensen [66].

15.11.2.1 Gene Duplication in the Opioid Family. An excellent example of gene duplication is found in the three branches of the opioid family. The large precursor molecule pro-opiomelanocortin (POMC) contains three similar amino acid sequences of α -, β -, and γ -MSH. POMC also contains ACTH and β -endorphin. Similarly, the proenkephalin molecule contains six copies of Met-enkephalin and one Leu-enkephalin sequence, while the third branch of the family, prodynorphin, contains three Leu-enkephalin sequences (Fig. 15.1). The ancestral gene for the opioids must have occurred very early in life as they are found in all living species, including invertebrates and plants. Opioid functions are discussed in Chapter 22 in Volume 2 of this handbook.

ACTH 1–39 and the peptide sequences within it (α -, β -, and γ -MSH) are collectively called the *melanocortins*. ACTH 1–39 possesses full biological activity, stimulating the adrenal cortex to produce glucocorticoids, which regulate carbohydrate and lipid metabolism, rapidly mobilizing carbohydrates from storage sites as well as suppressing the immune system. It also will darken the skin through the MSH

TABLE 15.2 Families of Mammalian Neuropeptides Based on Structural Similarities

Family	Abbreviation	Precursor
ACTH, MSH, and Opiates		
Adrenocorticotropin	ACTH	Pro-opiomelanocortin for all
Melanocyte-stimulating hormone	MSH	
β-Lipotropin		
β-Endorphin		
Bombesin-like Peptides		
Bombesin		Probombesin
Gastrin-releasing peptide	GRP	Pro-GRP
Neuromedin B	NMB	Pro-NMB
Rantensin		Pro-ranatensin RT
Calcitonin Gene-Related Peptides		
Calcitonin		Pro-calcitonin
Calcitonin gene-related peptide	CGRP	Pro-CGRP
Cholecystokinin		
Cholecystokinin	CCK	Pro-CCK
Gastrin		Progastrin
Enkephalins		
Met-enkephalin		Proenkephalin A
		Proenkephalin B
Leu-enkephalin		Proenkephalin A
		Proenkephalin B
Dynorphin		Proenkephalin B
Glucagon, Secretin		
Glucagon		Proglucagon
Secretin		Prosecretin
Vasoactive intestinal polypeptide	VIP	Pro-VIP/pro-PHI
Peptide histidine isoleucine	PHI	Pro-VIP/pro-PHI
Pituitary adenylate cyclase-activating peptide	PACAP	Pro-VIP/pro-PHI
Gastric-inhibitory peptide	GIP	Pro-GIP
Growth hormone-releasing hormone	GHRH	Pro-GHRH
Glycoprotein Hormones		
Thyroid-stimulating hormone	TSH	Pro-TSH
Follicle-stimulating hormone	FSH	Pro-LH/pro-FSH
Luteinizing hormone	LH	Pro-LH/pro-FSH
Chorionic gonadotropin	CG	Pro-CG
Insulin-like Growth Factors		
Insulin		
Insulin-like growth factors I and II		Proinsulin
Relaxin		Pro-IGF-I and -II
		Prorelaxin

(continued)

TABLE 15.2 (*Continued*)

Family	Abbreviation	Precursor
Neurotensin		
Neurotensin	NT	Proneurotensin/ proneuromedin
Neuromedin		Proneurotensin/ proneuromedin
Angiotensin II	AT-II	Proangiotensin
Oxytocin, Vasopressin		
Oxytocin	OT	Pro-OT/proneurophysin I
Vasopressin (antidiuretic hormone)	VP (ADH)	Pro-VP/proneurophysin II
Vasotocin		Provasotocin
Pancreatic Polypeptides		
Pancreatic polypeptide	PP	Pro-PP
Neuropeptide Y	NPY	Pro-NPY
Peptide YY	PYY	Pro-PYY
Somatotropins		
Growth hormone	GH	Pro-GH
Prolactin	PRL	Pro-PRL
Placental lactogen (choriomammotropin)	PL	Pro-PL
Tachykinins		
Substance P	SP	α -, β -, or γ -Protachykinins for these tachykinins
Neurokinin A	NKA	
Neurokinin B	NKB	
Tyr-MIF-1		
MIF-1		
Tyr-MIF-1		
Tyr-W-MIF-1		
Tyr-K-MIF-1

sequence (ACTH 1-13) and has potent neurotrophic influence on both the central and peripheral nervous systems. Separation of the peptide actions from the adrenocorticotrophic actions of ACTH 1-39 has been made possible by the separation or synthesis of noncorticotrophic fragments of the parent molecule, that is, chiefly α -MSH, and ACTH 4-9 and 4-10. These molecules are potent neurotrophic agents. They affect embryonic development and nerve regeneration, learning, memory, and attention in adults [5–7, 68–70]. An interesting bundling of different functions within a precursor molecule!

15.11.2.2 Gene Duplication in the Neurohypophyseal Family. The neurohypophyseal family of peptides OT and VP are found in all classes of vertebrates and all are nonopeptides. The VP-like peptides have in common a basic amino acid residue at position 8, whereas the OT-related peptides have a neutral amino acid in this

Figure 15.1 Structural relationships among prohormone, precursor forms of three main branches of opiate peptides, depicted as bar diagrams. The length in amino acid residues is indicated by the number at the corresponding C-terminus. Basic amino acids that are cleavage sites for processing are indicated by single or double vertical lines within the bars. SP, substance P; MSH, melanocyte-stimulating hormone; ACTH, adrenocorticotrophic hormone. (From [67], with permission from Oxford University Press.)

position. Duplication of the gene followed by mutation of residue 8 in one of the genes resulted in dual evolution of the two lines of peptides and their separate receptors (Fig. 15.2). Mammalian VP is probably derived from vasotocin, whereas the OT precursor was probably the mesotocin of amphibians. Precursor genes for these hormones existed in the animal kingdom before the divergence of vertebrates and invertebrates, perhaps 700 million years ago, and the processing machinery probably also predates divergence [71].

OT and VP are secreted by neurons in the supraoptic and paraventricular nuclei of the hypothalamus and stored in the posterior pituitary gland (neurohypophysis), from which they are secreted into the circulation. There is also a wide distribution of the axons of these hypothalamic neurons throughout the brain to regions that affect behavior and the regulation of reproductive events. In all species OT-like peptides are involved in reproduction and in mammals with milk ejection, uterine contractility, parturition, and female maternal, sexual, and social behavior. OT has behavioral properties opposite to those of VP; that is, OT may be an amnesic neuropeptide affecting consolidation and retrieval of memory, whereas VP has important effects on cognition [73] and has been reported to improve memory in diabetes insipidus patients [74].

VP-like peptides have antidiuretic and pressor functions. VP regulates water intake and diuresis and has important effects on the cardiovascular system. A mutation in the VP gene, if homozygous, results in diabetes insipidus, characterized by polyurea and polydipsia. Consequently *VP* is also referred to as antidiuretic hormone (*ADH*).

Figure 15.2 Hypothetical scheme of evolution of neurohypophyseal hormones. One gene duplication and a series of subsequent single substitutions in positions 3, 4, or 8 produce two molecular lines. The substituted amino acids and their positions in a hormone are listed to the right of each hormone. All oxytocin-like peptides have isoleucine, Ile in the 3rd position (Ile³), except pig. A, arginine; L, lysine. (From [72], with permission from The Royal Society (London).)

15.11.2.3 Duplication and Divergence in the NPY Family. NPY is a member of the pancreatic polypeptide (PP) family, which includes the gut endocrine peptide (PYY) and PP. NPY is found in abundance in the central and peripheral nervous systems. Each of these peptides consists of 36 amino acids and a C-terminal amide. NPY has been extremely well conserved during vertebrate evolution and is found in cartilaginous fish and even in the brain of cyclosomomes (lampreys), which diverged from the main vertebrate line about 450 million years ago [75]. The NPY family of homologous peptides arose as a series of gene duplications [76]. In contrast to the single ancestral NPY family gene, there are three Y subfamily receptors. Interestingly, these have evolved from seven Y receptor genes that resulted from chromosome quadruplication and subsequent loss of gene copies [77, 78]. NPY is involved in the regulation of many homeostatic functions as NPY neurons abundantly innervate the hypothalamus [79]. NPY is the most powerful physiological appetizer transducer known, and disorders in the complex humoral and circadian signals between NPY, leptin, and ghrelin promote hyperphagia and obesity [80]. The ability of PYY to curb appetite and its potential as an antiobesity drug have been topics of some controversy since first reported. McGowan and Bloom [81] conclude that while PYY has disadvantages in that it must be administered parenterally and has a short half-life, it has promising possibilities as an antiobesity drug in humans. NPY influences blood pressure, circadian rhythms, and sexual behavior. NPY also has been shown to modulate ethanol consumption [82]. There is considerable evidence that NPY acts to antagonize the behavioral consequences of stress [83], a topic that is discussed later in this chapter.

15.11.2.4 Gene Splicing. In addition to gene duplication, diversity of products in a single cell may result from splicing, a process in which introns, or parts of exons, are cut out. For example, the preprotachykinin gene can give rise to two mRNA molecules that code for SP and another two that code for both SP and another tachykinin, neurokinin (NK) [84].

15.12 ORGANIZATION OF NEUROPEPTIDE GENES

The isolation and characterization of POMC mRNA and the organization of the POMC gene have been extensively studied and serve as a model for most neuropeptides. The basic structure of the POMC gene has been highly conserved: It contains three exons and two introns. The large 3' exon contains the nucleotides coding for all the active neuropeptides. Exon 1 is a noncoding exon and exon 2 codes for the signal peptide [85]. The POMC gene has been localized on chromosome 2 in the human and chromosome 19 in the mouse [86]. Mutations affecting gene regulation may initiate or exacerbate neurological disease. New methods can rapidly and accurately identify likely neuropeptide gene regulatory regions using computer analysis of mouse, rat, and human genomic sequences. These identified sequences can then be analyzed in vivo using transgenic analysis. MacKenzie and Quinn [61] suggest that these technologies, combined with human polymorphic linkage analysis and association studies, may indicate how inappropriate regulation of neuropeptide gene expression may lead to human disease.

15.12.1 Regulation of Gene Expression

Neuropeptide gene expression is regulated by a complex series of negative and positive controls. In the anterior pituitary lobe, the secretion of POMC is stimulated by the hypothalamic secretion of CRH and VP and is inhibited by glucocorticoids from the adrenal cortex and from ACTH secreted by the anterior pituitary. Glucocorticoids decrease CRH mRNA in the paraventricular nucleus of the hypothalamus. In the intermediate lobe of the pituitary gland, the release of POMC is inhibited by the neurotransmitters dopamine and GABA. These secretory changes are preceded by appropriate increase or suppression of POMC mRNA activity in the pituitary. Hypothalamic POMC mRNA levels are also controlled by gonadal steroids, especially estrogen, which markedly reduces POMC mRNA [87].

15.13 BIOSYNTHESIS AND PROCESSING OF NEUROPEPTIDES

Like all polypeptides and proteins, neuropeptides are produced by cleavage from large precursor molecules synthesized on ribosomes and subsequently subjected to enzymatic proteolysis to yield neuropeptides of varying characteristics and potencies. Each peptide has an amino acid sequence determined by its corresponding gene. The nascent precursors are translocated through the intracellular membranes of the cell, chemically processed, packaged, and prepared for secretion.

15.13.1 Preprohormones

These are the initial precursor polypeptide chains that contain one or more amino acid sequences of the neuropeptide, one or more spacer (flanking) parts, plus the signal sequence at its N-terminus that guides it through the ribosome and into the lumen of the rough endoplasmic reticulum (RER). At this time the signal peptide is cleaved from the peptide chain by an endopeptidase [88]. The spacer parts lengthen the peptide to permit it to reach through the membranes to the inside of the RER.

15.13.2 Prohormones and Precursor Processing

The peptide chain with the signal peptide removed is the biologically inert *prohormone* containing one or multiple copies of the final active neuropeptides; thus this chain must be proteolytically processed into smaller active peptides which are then folded in the cisterna of the endoplasmic reticulum (ER) and shuttled to the *trans*-Golgi apparatus. Here they are packaged into secretory granules or vesicles that are budded off and in which posttranslational precursor processing occurs. This is the excision of peptide sequences from the prohormone by endopeptidases copackaged in the granules as the granules move down from the cell body to the nerve terminals [89]. The active peptide sequences to be excised are usually, but not always, flanked by dibasic amino acids, where cleavage occurs, first by endopeptidases, followed by exoproteolysis by amino- and carboxypeptidases, and in some cases by special amidating enzymes [90]. There may be additional enzymatic modifications such as glycosylation, phosphorylation, sulfation, or hydroxylation [91]. The precursor-processing endopeptidases are the *prohormone convertases* (PCs), which are found in all mammalian cells. Convertases are protease enzymes that clip off the active segments of the prohormone at single, specific basic residues or pairs of basic residues. There are several PCs, each of which is substrate specific [92, 93]. The prohormone convertase PC2 is believed to selectively convert multiple pro-neuropeptides into active peptides that function as neurotransmitters. Loss of PC2 results in changes of specific neuropeptides in certain tissues but not of all [94]. The specificity of the PCs and other proteases and their different distribution in neuroendocrine cells determine the time at which biologically active peptides are derived from the inactive precursor and thereby affect cellular development and activity [95]. Loss of the PCs in gene knockout experiments is lethal to embryos.

15.13.2.1 Role of Prohormones. Prohormones may have many different functions. Proinsulin ensures the correct folding and disulfide formation between the A and B chains of the insulin molecule. The neurophysins may serve a similar folding role for OT and VP. Prohormones vary considerably in size, but the size of the prohormone has little final relationship to the final size of the neuropeptide. The large prohormone proenkephalin gives rise to the five amino acid enkephalins. The complex prohormone POMC contains multiple neuropeptides that become active once the prohormone has been processed as well as some apparently biologically inert fragments (Fig. 15.1).

15.13.3 Tissue-Specific Processing

POMC was the first prohormone to be shown to be differentially processed in a tissue-specific way. In the anterior pituitary gland, cleavage of POMC by a PC yields chiefly a large N-terminal fragment ACTH 1-39 and β -lipotropin. In the intermediate lobe a different PC further hydrolyzes them to the shorter neuropeptides γ -lipotropin, β -endorphin, and α -MSH [92]. Thus the differential processing of a prohormone and its consequent yield may depend on variations in the relative amounts of the individual convertases with each tissue. Similarly, tissue-specific processing is found in the different cellular distribution of the PCs in the paraventricular nucleus and supraoptic nucleus, in which PC1 is colocalized with both OT and VP in intracellular secretory granules but PC5 is colocalized only with PC5. Differential processing of prohormones is an efficient method to achieve diversity in the nervous system.

15.14 INACTIVATION OF NEUROPEPTIDES

15.14.1 Intracellular Degradation

Degradation of neuropeptides to their inactive fragments or metabolites occurs in the RER or in the Golgi complex within about 30 min of their precursor synthesis, whereas later cleavages occur in the secretory granules in which the products may be stored for days. Thus the necessary enzymes must be present in the RER, Golgi complex, and secretory granules.

15.14.2 Extracellular Inactivation

Extracellular inactivation occurs rapidly through enzymatic degradation in plasma and by other cells, including glia, due to the widespread presence of peptidases. Most cell surface peptidases are anchored into the plasma membrane as integral membrane proteins. Those peptidases acting on small peptides belong to all groups of enzymes (endopeptidases, exopeptidases, and specialized peptidases), whereas those acting on larger proteins are endopeptidases that act internally in a peptide chain. A review of the structure and function of cell surface peptidases clarifies these differences [96].

An important cell surface peptidase, dipeptidyl-peptidase IV (DPP IV/CD26), selectively removes the N-terminal dipeptide with proline or alanine in the second position. Many neuropeptides are inactivated by DPP, making it an important physiological regulator, and DPP inhibitors, or peptide analogs resistant to DPP inactivation, are potential candidates for clinical use. The glucagon-like peptides (GLP-1 and GIP) are gastrointestinal peptides released after meals and are the most important secretins for insulin release. DPP rapidly degrades both peptides at the surface of endothelial cells or in plasma, resulting in a rapid loss of hormonal activity. DPP-resistant analogs of these neuropeptides theoretically could be of benefit in diabetic patients [97, 98].

Some cell surface proteases have dual effects: *inactivation* of one neuropeptide and *activation* of another. Angiotensin-activating enzyme (ACE) activates angiotensin I and inactivates bradykinin [99]. ACE activates angiotensin I, a decapeptide, by releasing a C-terminal dipeptide to form the octopeptide angiotensin II, a potent

vasopressor. Inhibitors of ACE are extensively used as antihypertensive drugs and for congestive heart failure. A similar role has been postulated for another cell surface endopeptidase, NEP, which may form functional complexes with ACE and peptide receptors on the cell surface that affect cellular signaling [100].

Neuropeptides are quickly inactivated in the gastrointestinal tract and are therefore ineffective if administered orally. However, peripherally administered neuropeptides bind tenaciously to cell membranes, which apparently protects them from proteolysis and permits them to perpetuate the cascade of receptor-mediated second-messenger effects for several hours.

15.15 NEUROPEPTIDE RECEPTORS

Neuropeptides, due to their insolubility in the cell membrane, must exert their effects by interacting with receptors on the cell surface. This interaction usually results in a change in the three-dimensional structure of the protein receptor, triggering a cascade of biochemical events in the cell and eventually leading to the specific cell response. Hormones, including neurohormones, exert their effects by binding to selective receptors on the target cell membrane. Hormone concentrations in vivo are normally very low, requiring that the receptor have a high affinity for that ligand. Hormone–receptor binding is reversible, resulting in the decay of the evoked effect after hormone removal or inactivation. A *high specificity* ensures that closely related neuropeptides, such as OT and VP, bind preferentially to their own receptors, but relative specificity is determined by the concentration of the hormone and its affinity of its receptor: At low concentrations VP will bind to its receptor and evoke pressor and antidiuretic effects; at high concentrations it can evoke the classic OT effects of uterine contractions and milk ejection.

Hormone receptors have the same properties as other cell surface receptors: They are finite in number so they are saturable, a characteristic of specific binding. However, receptor number can be increased (*upregulation*) or decreased (*down-regulation*) depending on the concentration of the hormone to which the receptor is exposed. Neuropeptides regulate the number and sensitivity of their own receptors. Insulin lowers the number of insulin receptors by decreasing receptor half-life [101].

15.15.1 Receptor Downregulation and Desensitization

Neuropeptides regulate the number and sensitivity of their own response. Desensitization is usually a decreased response to continued stimulation. Exposure to the agonist results in a peak in the response followed by a decline; subsequent exposure to the agonist evokes a smaller response, indicating desensitization due to sequestration of receptors (decreased receptor numbers) or loss of coupling to G proteins. After an extended time recovery occurs. Decreased receptor activity often involves phosphorylation of the receptor by a protein kinase, altering its conformation and changing its affinity for its ligand. Receptor phosphorylation is reversible by phosphatases.

Loss of receptors may also occur through endocytosis of the hormone–receptor complex after binding. This ends the first messenger signal and is an important part of desensitization. After acidification, the hormone is dissociated from its receptor

within the cytoplasm and receptors are returned to the Golgi apparatus, where they are recycled or degraded. Receptor number is also affected by the relative processes of receptor synthesis and degradation, actions that are affected by neuropeptides. Receptors are subjected to competition by closely related compounds and are profoundly affected by specific antagonists and drugs.

15.15.2 Receptor Upregulation and Sensitization

Chronic exposure to antagonists can increase receptor number. Several drugs such as lithium and antidepressant drugs alter the sensitivity of pre- and postsynaptic receptors, probably through an increase in neurotransmitter release.

15.15.3 Isoreceptors and Receptor Subtypes

Isoreceptors are structurally and functionally distinct receptors for the same hormone and all bind to the same natural hormone. They are mainly classified into subtypes by specific drug agonists and antagonists. The concept of multiple forms of receptors explains the subtle differences in the effects of closely related neuropeptides.

15.15.3.1 Arginine Vasopressin Receptors. The arginine vasopressin (AVP) receptor system is an example of neuropeptide receptor subtypes. AVP V1 and V2 receptors are differentially distributed in tissues and use different second messengers. The V1 receptor is widely distributed in brain and peripheral tissues and elicits glycogenolysis in liver and vasoconstriction in vascular smooth muscle through a cAMP-independent mechanism coupled to phosphoinositol turnover [102]. An effect on cardiac cells is also indicated as VP directly induces myocyte growth through the V1 receptor in neonatal rat heart cells [103]. The V2 receptor is coupled to cAMP and is located in the kidney where it mediates the important antidiuretic effects of AVP [104].

15.15.3.2 Neuropeptide Y Receptor System. In mammals this consists of three peptides and four to five G-protein-coupled receptors (GPCRs). The molecular evolution of the NPY receptor subtypes from seven Y receptor genes in gnathosomes to four to five in mammals is discussed by Larhammar and Salaneck [77]. NPY may act on virtually all hypothalamic neurons via one or several receptors, explaining the ability of NPY to regulate hypothalamic–pituitary axes influencing homeostatic behavioral and physiological functions, including appetite regulation, circadian rhythm and anxiety, as well as involvement in the response to stress. These receptors have been cloned and their differential distribution in the hypothalamus determined by various histological techniques [79, 105].

15.15.3.3 Tachykinin Receptors. The receptors of SP, neurokinin A, and neurokinin B have been cloned and classified into three groups: NK₁ (the predominant receptor for SP), NK₂, and NK₃, all of which are GPCRs. GPCRs may exist in a wide variety of different conformations, each of which has a different ability to recognize, desensitize, and stimulate effector systems, thus enabling the receptor to activate one or more G proteins in a ligand-specific manner [106–108]. Tachykinin are involved in a multitude of physiological functions due to their widespread

distribution, both centrally and peripherally. Peripherally tachykinins regulate blood flow and vascular permeability, salivation, and micturition. They are potent constrictors in smooth muscle and consequently are involved in gastrointestinal motility and intestinal secretions and are potent spasmogens of airway smooth muscle. Through the action of SP they function as pain transmitters from the periphery. Centrally, tachykinins act as neurotransmitters and neuromodulators in the spinal cord and SP regulates processes involving sensory perception (vision, olfaction, and audition) in addition to pain.

15.15.3.4 Melanocortin Receptors. Five types of melanocortin receptors have been cloned, and the markedly different effects of the melanocortins and various synthetic analogs on the adrenal cortex, melanoma cells, CNS neurons, and peripheral neurons can be explained on the basis of the differential distribution of the receptors in these tissues. See Adan and Gispen [109] and Strand [7, p. 283] for overviews. MC-1R is the MSH receptor and is specifically expressed in melanocytes and melanoma cells. MC-2R is an ACTH receptor and is localized in the adrenal cortex but also activates all MCRs. MC-3R, MC-4R, and MC-5R are the three neural receptors and their distribution may account for their effect on neural development, regeneration, and neuroprotection [109–111]; [7, p. 285]. The important role of brain α -MSH receptors and leptin in regulating food intake is discussed in Chapter 25 in Volume 3 of this handbook. Leptin regulates several neuropeptide genes, including POMC and NPY, and stimulates the hypothalamic expression of α -MSH, an orexigenic peptide, while inhibiting the release of melanocyte-concentrating hormone, an anorexic peptide [112].

15.16 NEUROPEPTIDE RECEPTORS AND SECOND-MESSENGER SYSTEMS

There are several different classes of neuropeptide receptors, classified on the basis of their structure and the second-messenger systems that they activate.

15.16.1 G-Protein-Coupled Receptors

More than 80% of neuropeptide receptors, most of which are glycosylated, are coupled to G proteins and stimulate adenylate cyclase and cAMP formation. GPCRs are characterized by a core of seven membrane-spanning helices connected by alternating cytoplasmic and extracytoplasmic loops with a central pore exposed to the extracellular surface. The specificity of the receptor depends on its distinct extracellular ligand binding domain. GPCRs are being intensely studied as potential targets of drug research due to the size and diversity of this receptor family as well as the high levels of specificity and sensitivity of the drugs affecting these receptors. GPCRs have recently been reviewed [113].

15.16.2 Phospholipase–Phosphatidylinositol Linked Messengers

The hydrolysis of PIP_2 is stimulated by the neuropeptides TSH, bombesin, VP, and GnRH, resulting in a cascade of phosphorylations that ultimately result in the specific response of the biochemical machinery of the cell.

15.16.3 Guanylate Cyclase (cGMP) Receptors

cGMP, unlike cAMP, is found in both the membrane and the cytoplasm. The soluble form of the enzyme is activated by nitric oxide (NO) and free radicals. Membrane-bound cGMP forms a transmembrane receptor complex for atrial natriuretic hormone (ANH), an important neuropeptide involved in electrolyte balance and cardiovascular homeostasis. Three natriuretic receptor subtypes have been cloned [17]. The ANH receptor has only one membrane-spanning helix and the extracellular binding site for neuropeptides is directly linked to the catalytic cGMP domain. cGMP is limited in its distribution with its highest concentration in the cerebellum, atrium of the heart, and kidney.

15.16.4 Tyrosine Kinase–Coupled Receptors

These receptors have only one membrane-spanning helix. The binding site is in the extracellular domain and the tyrosine kinases act by initiating a cascade of protein phosphorylations that are particularly important during development and growth. These are the receptors for insulin, insulin-like growth factor, and several other growth factors [114].

15.16.5 Cytokine Receptors

Cytokine receptors are transmembrane glycoproteins which are classified into various families. Type I consists of growth hormone (GH) and prolactin (PRL) and some of the interleukins, erythropoietin and ciliary neurotrophic factor. These receptors share some similarities with the tyrosine kinase receptors in that they have only one transmembrane helix.

15.17 HYPOTHALAMIC CONTROL OF THE PITUITARY GLAND

15.17.1 Hypothalamic Release-Stimulating and Release-Inhibiting Neuropeptides

Neuropeptides are especially concentrated in the CNS and the hypothalamus, median eminence, and pituitary gland contain the highest concentration of neuropeptides.

Hypothalamic control of anterior pituitary secretions is through neuropeptides that stimulate the release of pituitary hormones (RH) and those that inhibit pituitary secretion (IH). The *release-stimulating hormones* include CRH, GnRH, TRH (thyrotropin-releasing hormone), and growth hormone-releasing hormone (GHRH). The best evidence for a *release-inhibiting factor* is SRIF (somatotropin release-inhibiting factor), also called somatostatin, which inhibits the release of growth hormone, or somatotropin.

15.17.1.1 Control of Prolactin Release. Hypothalamic dopamine is the most potent *inhibitor* of prolactin release. However, a 38-residue hypothalamic peptide, pituitary adenylate cyclase-activating polypeptide (PACAP) is a potent *stimulator* of PRL release through its action on adenylate cyclase in the pituitary. PACAP stimulates PRL gene expression and POMC gene transcription. PACAP also stimulates

gonadotropin release from pituitary cells [115], and due to its widespread distribution in many tissues, PACAP has been shown to have important effects in malignant diseases and in immunology and inflammation [116, 117].

15.17.2 Hypothalamic–Pituitary Pathways

Hypothalamic control over the pituitary gland uses two different routes. In one route neurons from the dorsomedial and ventromedial nuclei (the parvocellular neurosecretory system of the hypothalamus) deposit their secretions in the medial eminence, where they enter a special *portal system* that leads to the anterior pituitary. Thus hypothalamic releasing and release-inhibiting neuropeptides pass through this special circulation, for example, GnRH, GHRH, CRH, TRH, and somatostatin. This is the *parvocellular system*. The second system, the *magnocellular system* [7, p 78], delivers the hypothalamic hormones OT and VP directly into the posterior pituitary through axons from cells within the paraventricular and supraoptic nuclei that extend through the infundibulum to the posterior pituitary.

15.17.3 Additional Pathways for Neuropeptide Delivery

Other pathways exist that indicate the complexity of the delivery of neuropeptides. The portal system may shunt blood retrogradely to the anterior pituitary, hypothalamus, and other brain regions, permitting hypothalamic and pituitary neuropeptides to reach distant parts of the brain through cerebrospinal fluid (CSF) flowing through the ventricles and the subarachnoid spaces. Specialized cells (tanycytes) in the floor of the third ventricle control access from neuropeptide-containing nerve terminals to the portal blood vessels. These various systems provide a selection of routes by which neuropeptides reach the brain and may affect phenomena as diverse as sleep, pain, orgasm, and headache [118].

15.18 BLOOD–BRAIN BARRIER

The BBB forms an effective structural barrier to the passage of large neuropeptides yet there is convincing evidence that systemically administered neuropeptides have potent effects on the CNS [1, 120, 121]. There are three main mechanisms by which neuropeptides cross the BBB and exert central effects:

1. *Penetration via Pores and Pinocytosis* The tight junctions in the BBB are not completely leakproof as a small amount of albumin can be seen in the CSF but it is only about 0.5% of plasma albumin concentration.
2. *Transmembrane Diffusion* Diffusion through the endothelial membrane depends on many physicochemical properties, including lipid solubility, molecular weight, ionization, and the ability to form electroneutral complexes. Several neuropeptides cross the BBB by this route, for example, the tripeptide TSH, MSH, insulin, and delta sleep-inducing peptide [122–125].
3. *Specific Carrier-Mediated Mechanisms* Water-soluble molecules such as glucose are transported almost exclusively by specific carrier-mediated transport

systems. These systems are saturable and highly stereospecific. Most transport systems are found in the choroid plexus or the capillary bed of the CNS. The specificity of these transport systems is indicated by the more than 10-fold variation in penetration for gastrin, delta sleep-inducing peptide, VIP, and calcitonin. Some neuropeptides are transported out of the brain but most are transported into the brain [123].

The peptide transport system-1 (PTS-1) transports small peptides with an N-terminal tyrosine, such as Tyr-MIF-1 (Tyr-Pro-Leu-Gly-NH₂), the analgesic peptides Met- and Leu-enkephalin, and dynorphin 1-8. A second system transports VP-like peptides in both directions. Arginine VP crosses intact from blood to brain and from brain to blood and also regulates the entry of several amino acids. Bradykin, angiotensin, and cytokines increase the permeability of the BBB to other neuropeptides. As a result of the differential penetration of neuropeptides, the composition of CSF is very different from that of plasma. The important role of the choroid plexuses in peptide transport and their significance in the delivery of drugs and peptide analogs to the brain are discussed by Smith et al. [126].

Neuropeptide penetration of the BBB may be increased by altering the physico-chemical properties of the synthetic neuropeptides, and their biological activity may be prolonged by peptidase inhibitors. The BBB may be modified by neurotoxins, neurotropic viruses, age, stress, and diurnal rhythms. It has been suggested that a faulty BBB may play a role in Alzheimer's disease, epilepsy, and paranoid psychosis.

15.19 ADMINISTRATION OF NEUROPEPTIDES

Oral administration of neuropeptides is ineffective due to inactivation by gastric and plasma peptidases. Peripheral administration by intraperitoneal injection is effective [3, 68, 127, 128], but due to the low penetration of the neuropeptides through the BBB, the concentration that reaches the brain may be insufficient in some cases. Subcutaneous injection is not effective. The method of choice now is central administration through intracerebroventricular or intrathecal injection. For chronic central administration, mini-osmopumps attached to intrathecal cannulae are used [129, 130]. Intranasal injection of some neuropeptides (e.g., VP) is highly efficient and the obvious choice of delivery clinically [131]. The disadvantage of all these methods is that they deliver either a single dose or a continuous dosage, whereas the physiological method is through pulsatile release of most hormones. Also the inverted *U-shaped dose-response curve* for administered neuropeptides is an important factor to remember when increasing the concentration of the peptide—higher dosages may decrease efficiency or even be ineffective [132].

15.20 TIME- AND TISSUE-SENSITIVE RESPONSES TO NEUROPEPTIDES

The effectiveness of neuropeptides may vary with the metabolic milieu, stage of development of the target tissue, and critical interaction with other growth factors, including the sex steroids. In both growing and regenerating systems, the melanocortins, for example, enhance growth processes but nevertheless constrain these

dynamic systems within normal physiological limits. They have little if any effect on stable, healthy full-grown neuromuscular systems. Hypophysectomized animals may respond robustly to the administration of neuropeptides that are ineffective in normal, healthy controls [132]. It is important to realize that neuropeptides may exert their main actions when the nervous system is stressed, challenged, or afflicted by disease [133–135].

15.21 NEUROPEPTIDE REDUNDANCY

There appears to be much redundancy in the actions of neuropeptides [136]. For example, many different neuropeptides (e.g., NPY, melanocortins, galanin, TSH, NPY, among others) have been reported to be active in nerve regeneration and development. The extensive evidence that melanocortins accelerate recovery from nerve trauma and affect the development of the neuromuscular system is described in several reviews [6, 69, 70]. However, these remarkable effects have not been translated into effective clinical trials. As similar neuroregenerative and neuroprotective effects have been described for several other neuropeptides, it is difficult to dissect out which particular neuropeptide is the most important. The failure of some knockout animals to display defects in phenotypes is particularly disturbing to the concept of neuropeptide-specific activity: One can only assume that a “fail-safe” redundancy has evolved to replace missing neuropeptides.

15.22 STRESS AND NEUROENDOCRINE RESPONSE

The hypothalamic–pituitary–adrenal (HPA) axis is the coordinator of the stress response, translating neural, endocrine, and cytokine information into physiological responses. Several CNS sites (e.g., cerebral cortex, amygdala, and hippocampus) deliver neural input to the hypothalamus [137]. In the hypothalamus these stimuli are transduced to neuroendocrine responses through the sequential stimulation of CRH, which together with the synergistic release of AVP and OT causes the secretion of ACTH, MSH, and the endorphins by the anterior pituitary. Endorphins, pain suppressors, are released in equimolar quantities as ACTH as a result of their simultaneous processing from POMC. Teleologically, this is a useful mechanism for ignoring pain while responding to stress in a “fight-or-flight” manner first described by Cannon and de la Paz [138]. These authors emphasized the role of the sympathetic nervous system in response to stress and it is this system, through the release of catecholamines, which is intimately involved in the activation of hypothalamic release of CRH. In turn, CRH activates the sympathoadrenal system as well as causing the release of pituitary ACTH, MSH, and the endorphins [139]. Catecholamines and the glucocorticoids together inhibit the immune system [140]. Either an over or understimulation of the HPA axis can have drastic effects. A hyperresponsive stress system, with prolonged exposure to ACTH-evoked glucocorticoids as a result of chronic stress, can cause hypertension and immunosuppression, with consequences seen only in a stressed or pathological condition. This may be due to the redundancy of some neuropeptides, leading to the assumption of the existence of a

“fail-safe” mechanism to vulnerability to inflammatory disease, hyperinsulinism and insulin resistance, hypertension, tachycardia, and Cushing’s disease. Glucocorticoids can have a wide range of deleterious effects on the brain, predominantly in the hippocampus [141]. A hyporesponsive stress system can be equally devastating, resulting in seasonal depression, chronic fatigue, and increased susceptibility to autoimmune and inflammatory diseases [142]. Catecholamine levels increase sharply in acute stress enabling the organism to tolerate the physiological trauma, but if the stress is prolonged or severe, catecholamine-caused vasoconstriction can be fatal [143]. Stress thus involves both the hypothalamic CRH circuits and the norepinephrine-containing brain neurons [139]. The entire stress-evoked circuits are replete with important negative- and positive-feedback systems.

An additional regulatory circuit evoked by stress involves the novel neuropeptide CART (cocaine- and amphetamine-regulated transcript) that may provide a link between the HPA, stress, and psychostimulant drugs. CART mRNA is increased in the striatum after the administration of cocaine and amphetamine, and CART is found in areas that regulate CRH, feeding and sensory processing, and other important physiological processes (for reviews see [144–148]). CART can affect CRH release from CRH-containing neurons in the paraventricular nucleus (PVN) and injection of CART into the PVN increases plasma ACTH and corticosterone [149]. CART also appears to be regulated by glucocorticoids [150]. The existence of these neuroendocrine links indicates the presence of multiple regulators of the organism’s ability to respond to stressful situations.

15.23 SUMMARY

The identification, characterization, and evolution of neuropeptides, neuropeptide families, and their receptors are discussed, including new information gleaned by genetic manipulations, peptidomics, and genomics. The flexibility of neuropeptides to act as neurohormones, neurotransmitters, and/or neuromodulators in regulating and modifying synaptic events is emphasized. Neuropeptide processing and inactivation are considered and the interesting phenomenon of tissue-specific processing of prohormones is introduced as an efficient method to achieve diversity in the nervous system. The hypothalamic control of the pituitary gland is outlined, as is the complexity of the pathways that permit the delivery of neuropeptides between these organs and to other sites in the brain. While the BBB prevents the passage of large neuropeptides, there are several mechanisms by which peripherally administered neuropeptides cross the BBB and exert central effects. Intracerebroventricular, intrathecal, and intranasal are other routes of effective administration of neuropeptides. Most studies have shown that the effectiveness of neuropeptides varies with the stage of development of the target tissue and the metabolic milieu, and many neuropeptides may be effective in replacing missing or defective neuropeptides. The vital role of the HPA axis in the coordination of the stress response and the clinical significance of a hyporesponsive versus a hyperresponsive HPA axis, involving the sympathoadrenal system, demonstrate the importance of the many negative- and positive-feedback systems that control these adaptive responses.

The now classic “*Vagusstoff*” studies of Otto Loewi in the 1920s provided the evidence for chemical-based signaling in the nervous system, and experiments performed in the decades that followed gave identities to many of these neurotransmitters. However, as recently as the 1950s, the fate of transmitter after its release from the presynaptic nerve terminal was still unclear. It was certainly known that transmitters such as acetylcholine (the *Vagusstoff*) were subject to enzymatic degradation. Less clear was whether neurotransmitter could also be recycled to the presynaptic neuron via some reuptake process. This possibility was verified by Hertting and Axelrod approximately four decades ago. They found that the synaptic actions of norepinephrine were attenuated by reuptake back into the nerve terminal from which it was released [1]. Subsequently, the reuptake process was found to be saturable and of high affinity, suggesting a specific process mediated by transporter proteins [2]. Thus the field of neurotransmitter transport was born. Elegant biochemical and pharmacological studies soon followed which delineated many of the functional properties of the transport process, and molecular biology approaches identified the different gene and protein families that act to move neurotransmitters across lipid membranes in brain.

We have learned much about the carrier-mediated transport of neurotransmitter in the past half-century. We know that some transporters reside on the plasma membrane of neurons and glia where they control ambient extracellular transmitter levels. Some plasma membrane transporters are expressed at high density at or near synapses where they can regulate neuronal signaling by sequestering transmitter away from neurotransmitter receptors and by preventing transmitter from spilling over to neighboring synapses. We know that these transporters recycle transmitter for rerelease or provide transmitter precursors for the synthesis of new transmitter. For example, presynaptic choline transporters provide choline for the synthesis of acetylcholine. Two glutamine transporters, one to efflux glutamine from glia and one to take up glutamine into neurons, are part of the glutamate–glutamine shuttle and are necessary for the synthesis of the amino acid transmitters glutamate and γ -aminobutyric acid (GABA). But neurotransmitter transporters are not only found on cell membranes; we know that transporters are also found on the membranes of transmitter-containing synaptic vesicles, where they act to fill synaptic vesicles from pools of cytoplasmic transmitter for subsequent activity- and calcium-dependent release.

We know that neurotransmitter transporters must typically move transmitter against the transmitter concentration gradient, and to do this they couple transmitter uptake to the electrochemical gradient of associated ions. We know that some transporters not only act as carriers of transmitter but also are permeable to ions, with conductances akin to those of ion channels; these different modes of activity suggest that transporters may have functions in neurons and glia that are distinct from their carrier roles. We know that transporter function can be regulated, that the regulation can affect the trafficking and subcellular distribution of transporters as well as their ability to flux transmitter, that the regulation can be both acute and chronic, and that this regulation can have physiological consequences.

We also know that these transporters represent the targets of drugs of abuse such as cocaine, amphetamine, and Ecstasy and therapeutic drugs for the treatment of diseases such as depression and epilepsy. We know that transporters can operate in reverse under certain conditions, which can be important in both normal and

abnormal neuronal function. We know that transporters are crucial for normal physiological activity in animals because genetically manipulated animals that lack particular transporters have striking phenotypes. And we know that naturally occurring transporter mutations and abnormal transporter function are associated with a variety of clinical phenotypes in humans.

In this chapter, we review many of these issues, beginning with a general examination of the different families of neurotransmitter transporters. We then examine the associations between transporter function, disease states, and clinical phenotypes. Finally, we provide two examples of chronic and acute regulation of transporter function.

16.1 NEUROTRANSMITTER TRANSPORTER FAMILIES

As discussed above, neurotransmitter transporters function to permit the movement of transmitter across biological membranes in both the peripheral and central nervous system (CNS). One can separate transporter families by where functional transporters are expressed. Plasma membrane neurotransmitter transporters of neurons and glia carry transmitter between the extracellular space and the cell cytoplasm; vesicular transporters in neurons carry transmitter between the cytoplasm and the vesicle interior.

Because neurotransmitter transporters allow for the electrochemical-driven movement of solutes across membranes, they have been assigned, based upon the Human Genome Nomenclature Committee Database, to the solute carrier (SLC) gene family, which includes 43 subfamilies and 298 transporter genes. A transporter is assigned to a specific SLC family if it has at least 20–25% amino acid sequence identity to other members of that family [3]. We subdivide our review of transporters based upon this classification scheme.

16.1.1 Plasma Membrane Neurotransmitter Transporters

The fidelity of synaptic transmission at chemical synapses depends on many factors. Two of these factors include maintaining low levels of ambient extracellular transmitter in order to prevent receptor overactivation or desensitization and rapidly sequestering transmitter away from receptor sites following transmitter release. These functions are carried out in part by transporters that reside on the plasma membrane of pre- and (in some cases) postsynaptic neurons or perisynaptic glial elements. In mammals, each small-molecular-weight neurotransmitter (the excitatory amino acid glutamate, the inhibitory amino acids GABA and glycine, and the monoamines dopamine, serotonin, and norepinephrine) has its own highly specific transporter proteins to carry out this action. The SLC1 (Na^+ -dependent) transporter family includes five transporters for glutamate. The SLC6 (Na^+/Cl^- -dependent) transporter family consists of genes that encode four GABA transporters, two glycine transporters, and one for each monoamine. In addition, there are three plasma membrane transporters for transmitter precursors. These include the choline transporter and two glutamine transporters. The general cellular localization of transporters at GABAergic and glutamatergic synapses is depicted in Figure 16.1.

Figure 16.1 Localization of neurotransmitter transporters. (a). GABA transporters (GATs) are localized on presynaptic nerve terminals of GABA neurons as well as glial cells at these synapses. GAT1 is predominantly expressed perisynaptically on the nerve terminal, while GAT 3 is localized to glial cells. The vesicular GABA transporter (VGAT) is expressed on vesicles in the presynaptic terminal, where it is responsible for the packaging of GABA for exocytosis. (b) At glutamatergic synapses, glutamate transporters are located on glial cells, as well as pre- and postsynaptic neurons. Excitatory amino acid transporters EAAT1 and 2, the predominant glutamate transporters, are expressed primarily on the glial cells surrounding the synapse. Other members of the glutamate transporter family are expressed more specifically, such as EAAT4, which is localized perisynaptically on postsynaptic Purkinje cells of the cerebellum. Glutamine transporters, which are required for uptake of the glutamate precursor molecule, are located both on presynaptic neurons and glial cells. System A subfamily glutamine transporters are found primarily on neurons, while system N are localized to astrocytes. Vesicular glutamate transporters (VGLUTs) are located intracellularly on the plasma membranes of neurotransmitter-containing vesicles.

16.1.1.1 Plasma Membrane Glutamate Transporters (SLC1). The SLC1 family consists of five high-affinity excitatory amino acid transporters (EAATs) [4, 5] for glutamate and two neutral amino acid transporters, ASCT1 and 2. EAAT1 (also known as GLAST, glutamate–aspartate transporter) and EAAT2 (also known as GLT-1, glutamate transporter) are the predominant glutamate transporters in glia, with EAAT1 prevalent in cerebellum and EAAT2 in forebrain. In contrast, EAAT3 and 4 are primarily expressed in neurons, with EAAT3 widely expressed in various brain areas and EAAT4 mostly confined to the dendrites of Purkinje cells in the cerebellum [6, 7]. Thus, EAAT4 is a postsynaptically localized transporter. EAAT5 is present in both neurons and glia in the retina. It is associated with rod photoreceptors and bipolar cells and is therefore thought to participate in the processing of visual information [8]. Neuronal EAAT3 and EAAT4 are typically localized extrasynaptically and contribute less significantly to glutamate uptake in the brain than the two astroglial transporters. EAAT3 is also localized to presynaptic GABA-containing terminals and may play a role in providing glutamate for GABA metabolism [9].

The predominant substrates for glutamate transporters are L-glutamate and D/L-aspartate. During each transport cycle, three Na^+ ions and one H^+ ion are

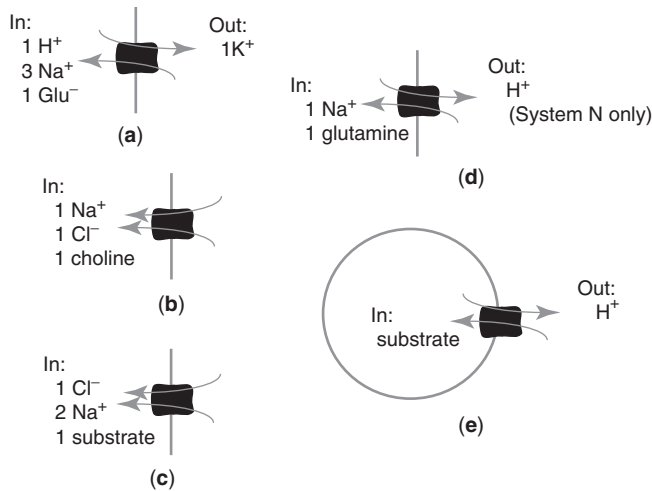

Figure 16.2 Stoichiometry of neurotransmitter transporters. (a) The SLC 1 family includes the five high-affinity glutamate transporters (EAAC1, GLT-1, GLAST, EAAT4, and EAAT5), which transport glutamate and aspartate into the cell accompanied by cotransport of 1 H^+ and 3 Na^+ and countertransport of 1 K^+ . (b) Choline transporters are members of the sodium/glucose transport (SLC5) family, which includes 220 members in the animal and bacteria kingdoms. The choline transporter (SLC5A7) couples the transport of choline to the influx of Na^+ and Cl^- down their gradients. (c) The SLC6 family contains the transporters for GABA, glycine, norepinephrine (NE), 5-hydroxytryptamine (5-HT), and dopamine (DA). These transporters generally couple substrate transport to the influx of Na^+ and Cl^- , although the serotonin transporter also transports a K^+ ion along with this cargo. (d) The SLC38 family contains two types of glutamine transporters, divided into system A and system N. System-A-type glutamine transporters likely cotransport their substrate along with 1 Na^+ , while system-N subfamily transporters likely cotransport a Na^+ ion and antiport a proton. (e) Vesicular neurotransmitter transporters are grouped into SLC families 17, 18, and 32. These transporters are driven by the electrochemical gradient that is generated by the vacuolar ATPase (V-ATPase), which translocates protons into the vesicle. The vesicular transporters use this gradient to transport substrate into the vesicle coupled to the outward transport of one or more H^+ ions.

cotransported along with the amino acid, and one K^+ ion is countertransported (Fig. 16.2a). This stoichiometry of transport permits a transmembrane glutamate concentration gradient ($[\text{Glu}]_{\text{in}}/[\text{Glu}]_{\text{out}}$) of approximately 100 to be achieved by glutamate transporters under normal circumstances; thus, glutamate transporters can maintain an ambient extracellular glutamate concentration in the low-nanomolar range [10]. When this electrochemical gradient collapses under pathological circumstances, such as during ischemia, the equilibrium state of the transporter shifts, and extracellular glutamate concentrations can rise to high-micromolar levels [11]. The reliance of transporters on the electrochemical gradient for transmitter transport underlies the hypothesis of transporter-mediated excitotoxicity, a leading theory for massive neuronal death observed in various pathological states [12–14]. This phenomenon will be further discussed in relation to its clinical implications later in this chapter.

Structurally, hydropathy analysis predicts a protein topology of eight transmembrane domains (TMDs) connected by alternating extracellular and intracellular

loops, intracellular N- and C-termini, and a large extracellular loop between TMDs 3 and 4 [15, 16]. A unique, highly conserved and long hydrophobic stretch of amino acids is located near the C-terminus and is believed to be responsible for substrate binding and translocation. Between TMDs 7 and 8, there is a “reentrant loop” that likely forms part of the pathway for the translocation of substrates and cotransported ions, similar to that found in many ligand- and voltage-gated ion channels [17] (Fig. 16.3a). The three-dimensional structure of glutamate transporters predicted by freeze-fracture electron microscopy suggests that functional EAAT3 is expressed as a distinct pentagonal 10-nm-diameter particle in the plasma membrane [18], supporting evidence for an oligomeric structure to glutamate transporters [19]. Recently, the crystal structure of a bacterial homologue to plasma membrane glutamate transporters was reported [20]. This transporter has a trimeric structure with a bowl that extends down to the midpoint of the lipid bilayer. At the base of the bowl are binding sites. The movement of nearby helices may allow for these binding sites to have alternating access to each side of the membrane.

How transporter structure maps onto transporter translocation of substrates has been of considerable interest not only for glutamate transporters but also for all neurotransmitter transporters. The classic translocation model is that of alternating access: Substrates attach to their binding sites in a stoichiometric fashion on one side of the membrane; a conformational change of the protein then occurs such that the binding sites are relocated to the opposite side of the membrane; lastly, the substrates unload and the transporter resets to its initial state. This model accounts for some but not all of the recent physiological data. To account for these data, more recent models argue for either variations in alternating access [21, 22] or transport schemes more similar to flux through ion channels [23]. Although the glutamate transport

Figure 16.3 Schematic topology of plasma membrane transporters: (a) SLC 1 (glutamate transporters); (b) SLC 5 (choline transporters); (c) SLC 6 (GABA, glycine, and monoamine transporters); (d) SLC 38 (glutamine transporters).

cycle described above is consistent with the alternating access model, it is also known that glutamate transporters can behave as glutamate-activated Cl^- channels; Cl^- is not required for glutamate transport [24]. These glutamate-activated Cl^- currents regulate membrane potentials and affect synaptic signaling [25].

The indispensable role of glial glutamate transporters in controlling extracellular glutamate levels is prominently illustrated in GLT1 or GLAST knockout mice. Less than 10% of total glutamate transporter is retained in the CNS of GLT1 null mice. These mice suffer from lethal spontaneous seizures and increased susceptibility to acute cortical injury. Most of them die by postnatal week 6 [26]. Knockout of GLAST, a transporter that is abundant in cerebellum, leads to impairment in coordinated motion and increased cerebellar vulnerability after acute brain injury [27].

Once taken up by astrocytic glutamate transporters, glutamate is metabolized via two major pathways: conversion to glutamine or entrance into the tricarboxylic acid (TCA) cycle. Formation of glutamine, which is the precursor not only for glutamate but also for GABA and glycine, is catalyzed by glutamine synthetase. Alternatively, glutamate can function as a substrate for the TCA cycle, in which it is converted to 2-oxoglutarate (2-OG) for energy metabolism [28]. Recent evidence also connects glutamate transport with the classic role of astrocytes in providing lactate to neurons as an energy source. In this model [29], glutamate released upon synaptic activity is taken up by astrocytes. Three Na^+ ions cotransported with glutamate into the astrocyte trigger adenosine triphosphatase (ATPase) activity to extrude the intracellular sodium load. The drop in ATP levels leads to aerobic glycolysis in which lactate is synthesized. The lactate is then shuttled back to neurons to fuel neuronal activity, including synaptic transmission. Glucose utilization and lactate secretion are decreased in GLT1 and GLAST mutant mice. This reduction in glucose utilization has been directly linked to the decrease in Na^+ cotransport into the astrocyte in these transporter-deficient mice [30].

16.1.1.2 Na^+/Cl^- -Dependent Neurotransmitter Transporters (SLC6). This family of transporters translocates substrates across the plasma membrane by coupling this process to the movement of Na^+ and Cl^- transport down their electrochemical gradients (Fig. 16.2c). Family members include the transporters for the inhibitory neurotransmitters GABA and glycine and the biogenic amine transmitters norepinephrine, dopamine, and 5-HT. Although we will not discuss this in detail, this family also contains the transporters for the osmolytes betaine and taurine, the amino acid proline, and the metabolic compound creatine [31]. Members of this family encode proteins of approximately 600 amino acids that have 12 TMDs, with N- and C-termini exposed to the cytosol and a large extracellular loop between TMDs 3 and 4 (Fig. 16.3c).

16.1.1.2.1 GABA Transporters (GATs). There are three GABA transporters, although a fourth, the betaine transporter, can also transport GABA. GAT1 [32] is the predominant GABA transporter in brain and is distributed widely. It is expressed at the highest density in the olfactory bulb, superior colliculus, substantia nigra, and magnocellular nucleus of the lateral hypothalamus; there is moderate expression in the hippocampus, cerebral cortex, pons, and granule layer of the cerebellum; its lowest expression is in cerebellar white matter, thalamus, and striatum [33]. Quantitative fluorescence indicates that GAT1 expression is, on average, on the order

of 1000 transporters/ μm^2 , with approximately 30–50% of them on the plasma membrane at any given time [33, 34]. GAT2 is found in meninges, ependyma, and choroid plexus. It does not overlap with markers of GABAergic signaling [35], and its interesting tissue distribution suggests that the transporter likely participates in regulating osmotic balance or GABA levels at the blood–brain barrier and in cerebrospinal fluid. GAT3 is found in neurons but is much more highly expressed in glia and its localization suggests a significant role in GABAergic signaling (Fig. 16.1a) [35].

The majority of functional data come from studies of GAT1. GAT1 likely functions as an oligomer [36]. Interaction between the fourth intracellular loop and the cytoplasmic N-terminus affects substrate translocation [37], while residues in the N-terminus affect the reorientation of the unliganded transporter [38]. The transport is electrogenic, with a stoichiometry of $2 \text{ Na}^+ : 1 \text{ Cl}^- : 1 \text{ GABA}$ (Fig. 16.2c). Chloride is required but does not contribute to the net charge transported per transport cycle and so may not unload during the cycle [39].

Even though the rate of GABA transport (tens of molecules per second) is too slow to respond to fast synaptic transmission, GAT1 is thought to provide binding sites for GABA, thus sequestering GABA from binding to GABA_A and GABA_B receptors [31]. In retina, reverse transport of GABA via GAT1 upon membrane depolarization contributes to the non-calcium-dependent release of GABA; calcium-dependent transmitter release may not occur in these cells [40]. In GAT1-deficient mice, the extracellular GABA level is increased. This results in an overactivation of GABA_A receptors and a postsynaptic tonic conductance. Moreover, chronically elevated GABA levels also downregulate phasic GABA release and reduce pre-synaptic signaling via GABA_B receptors, which results in an enhanced tonic and a diminished phasic inhibition [41]. Recently, it has been shown in cultures of midbrain neurons that currents mediated by the GABA transporter result in action potentials in these neurons. These transporter-initiated signals may be important in opiate withdrawal [42].

16.1.1.2.2 Glycine Transporters (GlyTs). Two isoforms of GlyT exist: GlyT1 is the predominant glial glycine transporter, whereas GlyT2 expression is restricted to neurons at glycinergic nerve terminals. The two isoforms have different stoichiometries: GlyT2 has a stoichiometry of $3 \text{ Na}^+ : 1 \text{ Cl}^- : 1 \text{ glycine}$, which predicts effective glycine uptake under all physiological conditions. In contrast, GlyT1 has a stoichiometry of $2 \text{ Na}^+ : 1 \text{ Cl}^- : 1 \text{ glycine}$, which suggests that the direction of glycine transport will be dictated by physiological conditions [43].

GlyT2 is the primary uptake site at inhibitory glycinergic synapses and thus likely regulates glycine signaling [44]. In addition to expression in glia at glycinergic synapses, GlyT1 is also expressed at glutamatergic synapses containing NMDA receptors. GlyT1 is involved in regulating glycine levels at the coagonist binding sites of these receptors [45]. GlyT1 knockout mice display severe motor deficits accompanied by lethargy, hypotonia, and hyporesponsivity. They usually die in the first day after birth due to respiratory failure, suggesting a role of GlyT1 in regulating centrally generated motor rhythms [46, 47].

16.1.1.2.3 Dopamine Transporters (DATs). In the brain, DAT distribution correlates well with dopaminergic innervation, with the highest density in striatum (including

putamen, caudate nucleus, and nucleus accumbens) and olfactory tubercle [48, 49]. Subcellularly, they are found in all neuronal processes and colocalize with markers for tyrosine hydroxylase and dopamine D₂ receptors [3]. The wide distribution of DATs beyond dopaminergic synaptic junctions suggests a role for DATs in regulating extracellular dopamine levels extrasynaptically [50].

DAT is a 620-amino-acid protein with a large hydrophilic extracellular loop between TMDs 3 and 4 containing two to four potential glycosylation sites (Fig. 16.3c). Dopamine is the major substrate for DAT, which also mediates uptake of norepinephrine, albeit inefficiently [51]. Other substrates include sympathomimetic amines, amphetamines, and the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Cocaine is a high-affinity DAT antagonist. The stoichiometry of the dopamine uptake process is $2 \text{ Na}^+ : 1 \text{ Cl}^- : 1 \text{ dopamine}$, and therefore two positive charges are translocated with each dopamine molecule [52]. Such Na^+ influx accompanying inward transport of amphetamine (AMPH) is crucial for AMPH-induced dopamine efflux [53]. In addition to uptake, DATs also conduct an ion-channel-like inward current which results in an excitatory response in dopamine neurons at lower dopamine concentrations than that required for dopamine auto-receptor activation [54]. These DAT-associated currents may modulate excitability and regulate release of neurotransmitter from midbrain dopamine neurons.

Dopamine is involved in movement, cognition, attention, reward, goal-directed behavior, and blood pressure regulation [55]. DAT, which clears dopamine from the extracellular space, likely serves as an important regulator of signaling at dopaminergic synapses. Dopamine efflux through DAT contributes to autoinhibition of dopaminergic neurons [56]. In DAT knockout mice, dopamine persists at least 100 times longer in the extracellular space, leading to multifold increases in extracellular dopamine levels. These animals exhibit spontaneous hyperlocomotion and have cognitive deficits. Young homozygous DAT knockout animals gain weight slowly and show a significant propensity for premature death due to impaired food intake. Moreover, the ability of amphetamine and cocaine to elevate locomotor activity is abolished in these mice, even though self-administration of cocaine is preserved [57]. These results support a role for DAT in the behavioral action of addictive drugs. However, targets other than DAT likely contribute to the rewarding properties of cocaine in these mice [51].

16.1.1.2.4 Norepinephrine Transporters (NETs). NET is distributed widely in the central and peripheral nervous systems and is also found in a subset of adrenal chromaffin cells. In the adult brain, NET is confined to noradrenergic neuronal processes, including extensive arborizations within the hippocampus and cortex. Significant colocalization is seen with the axonal markers syntaxin, synaptophysin, and synaptosomal-associated protein (25 kD) (SNAP-25) [58].

NET is a 617-amino-acid protein that transports both norepinephrine and dopamine as well as other substrates, including sympathomimetic amines [59]. It is a major target of antidepressants and several psychostimulants. The stoichiometry of NET is $1 \text{ Na}^+ : 1 \text{ Cl}^- : 1 \text{ norepinephrine}$ and is therefore electrogenic [60]. Occasionally, NET switches to a channel mode during the transport cycle to allow a large influx of norepinephrine along with associated ions [61]. Structurally, N-glycosylation of NET is crucial for stabilizing surface expression but not for ligand recognition [62].

As with many members of this transporter family, NET is likely involved in termination of norepinephrine transmission. Consequently it is likely to regulate many central and sympathetic nervous system functions, including learning and memory, mood, attention, stress, and blood flow. NET knockout mice are viable and fertile but show reduced body temperature (1°C lower) and reduced body weight (20% less). These mice also display features similar to wild-type animals treated with antidepressants. Both cocaine and amphetamine are more effective in stimulating locomotion in NET knockout mice [63].

16.1.1.2.5 Serotonin transporters (SERTs). SERT is distributed widely in the central and peripheral nervous systems. In brain, SERT is highly concentrated in prefrontal cortex and raphe nuclei. Subcellularly, it resides at perisynaptic sites all along the axonal membrane, although somatodendritic uptake of 5-HT has also been observed [64, 65]. During development, SERT has also been found at glutamatergic thalamocortical afferents [66, 67]. Since the machinery to synthesize 5-HT is not present in these glutamate-containing neurons, it is suggested that thalamocortical afferents “borrow” 5-HT via transporter uptake and release it during the postnatal period in which SERT is expressed [67].

SERT, a protein of 630 amino acids, transports 5-HT as well as a variety of tryptamine derivatives. It is the primary target for several antidepressants and psychostimulants, including cocaine and (+)-3,4-methylenedioxymethamphetamine (MDMA, ‘Ecstasy’). The transport of 5-HT by SERT requires not only Na^+ and Cl^- but also countertransport of K^+ . The stoichiometry of transport suggests that transport should be nonelectrogenic [68]. However, channellike ion fluxes are observed in SERT both in the presence and absence of 5-HT [69], and SERT may switch from electrogenic modes to nonelectrogenic modes under different physiological conditions [70].

As its distribution indicates, SERT likely participates in serotonergic transmission and thus is involved in a variety of 5-HT-mediated behaviors, including mood, aggression, appetite, sleep, cognition, and motor activity. In SERT knockout mice, disruption of 5-HT uptake increases the extracellular concentration of 5-HT sixfold and reduces intracellular 5-HT by 60–80%. The amphetamine-induced locomotion-enhancing effect in these animals is also disrupted, although the ability to become addicted to psychostimulants is preserved [71]. Double-knockout mice lacking both DAT and SERT fail to show place preference for cocaine, indicating that both transporters are involved in cocaine-induced drug reward [72]. SERT and NET double-knockout mice show enhanced response to cocaine, suggesting a dopamine-independent role for norepinephrine signaling in cocaine action [73].

16.1.1.3 Choline Transporters (SLC5). Acetylcholine (ACh) is synthesized from choline and acetyl coenzyme A by the enzyme choline acetyltransferase (CHAT) in cholinergic nerve terminals. It is then transported into synaptic vesicles by the vesicular acetylcholine transporter (VACHT; see below) and released from the nerve terminal upon stimulation. After release into synaptic cleft, ACh is rapidly hydrolyzed into choline and acetate by the enzyme acetylcholinesterase. Choline is then taken up to presynaptic terminal for recycling by the choline transporter (CHT). This process is thought to be the rate-limiting step in ACh synthesis [74, 75].

CHT is expressed exclusively in cholinergic neurons and correlates very highly with the distribution of VACHT and CHAT. Subcellularly, CHT is highly concentrated at presynaptic cholinergic terminals. The majority of CHT expression is on small synaptic vesicles in the nerve terminal, with very little expression on the plasma membrane [76]. Thus CHT may only be plasma membrane resident during the time that vesicles containing ACh are fusing with the plasma membrane during neurotransmission. CHT is a high-affinity ($K_m < 10 \mu\text{M}$), Na^+/Cl^- -dependent transporter which belongs to the family of Na^+ -dependent glucose transporters. This family of transporters utilizes the Na^+ electrochemical gradient to drive the coupled transport of a variety of substrates (sugars, amino acids, vitamins, urea, and anions), as shown in Figure 16.2b. [77]. CHT, a 580-amino-acid protein, is predicted to have 13 transmembrane segments with an extracellular N-terminus and a large intracellular C-terminus (Fig. 16.3b) [78].

In CHT knockout mice, hemicholinium-3-sensitive choline uptake and subsequent ACh synthesis are specifically lost. Although morphologically normal at birth, homozygous CHT(–/–) mice become immobile, breathe irregularly, appear cyanotic, and die within an hour. Adult heterozygous CHT knockout mice overcome the reductions in CHT protein levels and sustain choline uptake activity through posttranslational mechanisms [79].

Traditionally, a transporter for ACh was thought unnecessary, given the high efficiency of acetylcholinesterase and the presynaptic reuptake of choline by high-affinity CHT. However, a recent study has documented the existence of a novel ACh transporter coded by the gene *snf-6* in *Caenorhabditis elegans*. Alignment of the predicted amino acid sequence of *snf-6* reveals 30–40% identity to members of the SLC6 transporter family [80]. Whether proteins of similar function also exist in mammals remains to be determined.

16.1.1.4 Glutamine Transporters (SLC38). As mentioned previously, glutamine is the precursor for synthesizing glutamate and GABA. Neuronally released glutamate is transported into astrocytes by plasma membrane glutamate transporters. Glutamate is converted to glutamine by glutamine synthetase. The glutamine must then be shuttled to neurons for amino acid synthesis. Glutamine is released from astrocytes in a nonexocytic manner and then picked up by the nerve terminal for use [81, 82]. Both processes are mediated by glutamine transporters, which belong to the family of Na^+ -dependent neutral amino acid (system N/A) transporters. The former process is mediated by the system N transporter on the plasma membrane of astrocytes. The latter process is mediated by the system A transporter on the plasma membrane of neurons [83, 84]. The system A and system N transporters each flux small, neutral amino acids, with a wider range of substrates for system A transporters. Each exhibit profound inhibition at low extracellular pH, which, in the case of system N subtypes but not system A, arises from the coupled countertransport of protons (Fig. 16.2d) [85]. Hydropathy analysis predicts a primary structure of 11 transmembrane segments, with an extracellular C-terminus and intracellular N-terminus. Between TMDs 5 and 6, there is a large loop exposed to the extracellular space [86] (Fig. 16.3d).

16.1.2 Vesicular Neurotransmitter Transporters

Neurotransmitters are synthesized in neurons and then must be concentrated in vesicles for subsequent Ca^{2+} -dependent release. The amount of transmitter

necessary for efficient synaptic transmission requires that each vesicle contain high-millimolar levels of neurotransmitter. Thus, vesicular transporters are absolutely required for normal brain function. However, vesicular transporters play other roles as well. The accumulation of neurotransmitter into vesicles acts as an amplification step for Na^+ -dependent uptake between the extracellular space and the cytoplasm as it increases the concentration gradient across the plasma membrane. Moreover, vesicular accumulation of neurotransmitter prevents the toxic effects that high transmitter concentrations might exert if present in the cytoplasm. Vesicular transport has been observed for all molecular weight transmitters, including ACh [87], the monoamines [88], glutamate [89], GABA [90], and glycine [91]. Transport by these carriers is driven by the proton electrochemical gradient ($\Delta\psi$) generated by the vacuolar ATPase that utilizes the energy of cytoplasmic ATP to translocate H^+ into vesicles and acidifies the organelle lumen (Fig. 16.2e) [92, 93]. Thus, all vesicular transporters are proton antiporters.

Based on sequence similarity and substrate binding, vesicular transporters can be divided into three families: the SLC17 transporter family for organic anions, including three vesicular transporters for glutamate (VGLUT 1–3), the SLC18 transporter family of vesicular amine transporters, including a VACHT and two for monoamines (VMAT 1–2), and the SLC32 transporter family for inhibitory amino acids, which includes vesicular transporters for GABA and glycine (VIAAT/VGAT). The structures of the vesicular transporter families are illustrated in Figure 16.4.

16.1.2.1 Vesicular Glutamate Transporters (SLC17). VGLUT 1 and 2 are localized exclusively in glutamatergic neurons of the brain and specifically at synaptic vesicles [94]. The distribution of VGLUT3 largely overlaps those of VGLUT 1 and 2. However, colocalization study indicates that VGLUT3 is also present in GABAergic interneurons, neuromodulatory neurons, and astrocytes. In addition to synaptic vesicles, VGLUT3 resides on vesicular structures of astrocytes and neuronal dendrites, suggesting novel roles for this transporter [95, 96]. The three types of VGLUT consist of 600-amino-acid residues and have been identified to contain 10 putative transmembrane domains with N- and C-termini exposed to cytosol (Fig. 16.4a). The three VGLUTs exhibit saturable glutamate transport with a K_m of approximately 1 mM [97, 98]. The stoichiometry of VGLUTs has not yet been determined but may vary for different isoforms [99, 100]. In contrast to other isoforms, VGLUT1 mediates a chloride conductance which could act to diminish $\Delta\psi$ and consequently regulate glutamate metabolism and synaptic release of transmitters [101].

16.1.2.2 Vesicular Acetylcholine and Monoamine Transporters (SLC18). VACHT is a unique marker for cholinergic synapses and neuromuscular junctions. It is coexpressed invariably with choline acetyltransferase [102]. Two isoforms of vesicular monoamine transporters exist: VMAT2 is found exclusively in monoaminergic neurons [103] while VMAT1 resides in neuroendocrine cells. Subcellularly, VACHT resides on small, clear synaptic vesicles of axon terminals that make symmetric contacts with dendrites [104]. VMAT2 is also expressed in small synaptic vesicles, but its major location in axon terminals is on large, dense core vesicles, which supports the role of large, dense core vesicles in the storage and release of monoamines [103]. Somatic and dendritic expression has also been observed for both VACHT and VMAT2, suggesting that these transmitters could be stored and released at these

Figure 16.4 Schematic topology of vesicular neurotransmitter transporters: (a) SLC 17 (vesicular glutamate transporters); (b) SLC 18 (vesicular acetylcholine transporter and vesicular monoamine transporters); (c) SLC 32 (vesicular inhibitory amino acid transporters).

atypical sites [105]. Hydropathy analysis predicts 12 putative transmembrane segments, with a large hydrophilic loop between TMDs 1 and 2. This loop has been proposed to be inside the lumen of the vesicle, whereas both the N- and C-termini are likely to be cytoplasmic [106] (Fig. 16.4b).

VACHT and VMATs transport a single positively charged molecule into vesicles with a 2 proton : 1 amine stoichiometry. This predicts a transmitter accumulation into vesicles of approximately 500 mM [107]. Besides monoamines, VMAT2 transports dopaminergic neurotoxins such as 1-methyl-4-phenyl-phenylpyridinium (MPP⁺) from the neuronal cytoplasm into synaptic vesicles, from which amphetamines can induce their release.

Homozygous knockout of VACHT leads to failure of cholinergic neurotransmission in *C. elegans*, and homozygous knockout of VMAT in the worm leads to an egg-laying- and locomotion-defective phenotype similar to treatment with the VMAT inhibitor reserpine [108, 109]. VMAT2(−/−) animals exhibit marked deficits in locomotor activity and feeding behavior and die shortly after birth [110, 111]. These animals can

be partially rescued by amphetamine, which stimulates biogenic amine efflux through plasma membrane amine transporters. This is consistent with the observation that increased locomotor activity evoked by acute treatment with amphetamine is significantly higher in heterozygous VMAT2(+/-) mice than in wild-type mice [112]. The brains on the VMAT2 knockout mice show no gross morphological changes, and monoaminergic pathways do not appear altered [110, 112].

16.1.2.3 Vesicular Inhibitory Amino Acid Transporters (SLC32). VIAAT/VGAT is a neuronal vesicular transporter for both GABA and glycine. Therefore, the protein has been observed in GABAergic as well as glycinergic terminal boutons. Subcellularly, VIAAT/VGAT is restricted to small synaptic vesicles, as expected [113, 114]. Its putative structure predicts 10 TMDs, a long amino terminus and a short carboxyl terminus, and a large intraluminal loop between transmembranes 1 and 2 [115] (Fig. 16.4c).

VIAAT/VGAT transports GABA, glycine, and β -alanine into synaptic vesicles, with a stoichiometry of 1 proton : 1 amino acid [113]. The affinities of the transporter for GABA and glycine are approximately 5 and 25 mM, respectively. These low affinities may not be surprising given the relative abundance of these amino acids in the cytoplasm.

16.2 CLINICAL RELEVANCE OF NEUROTRANSMITTER TRANSPORTERS

Since vesicular transporters are responsible for determining the amount of transmitter released into the extracellular space and plasma membrane neurotransmitter transporters are essential for setting ambient levels of extracellular neurotransmitter, reduced or altered transporter function is likely to result in abnormal transmitter levels, improper cell signaling, and both acute and chronic pathophysiological states. Evidence relating neurotransmitter transporters to specific disorders comes from studies of transporter expression and function in human patients as well as studies of animal models and transporter knockouts.

16.2.1 Plasma Membrane Glutamate Transporters

Because glutamate is the most prevalent excitatory neurotransmitter in the brain, its regulation has an especially large impact on CNS function. Altered glutamate transporter expression and function are associated with a number of prevalent diseases, including amyotrophic lateral sclerosis (ALS), Alzheimer's disease (AD), Huntington's disease, epilepsy, stroke, and glioma. The mechanism most often linked to these disorders is glutamate-induced excitotoxicity, which, as discussed above, could result from normal glutamate transporter function during pathophysiological conditions, or abnormal transporter expression or function.

A specific role for the glutamate transporter in human pathology has been most clearly elucidated for the motor neurodegenerative disease ALS. In humans, a majority of ALS patients show specific loss of EAAT2 in the motor cortex and spinal cord [116]. One possible explanation is that the loss of glutamate transporter protein is due to abnormally truncated RNA species, which have been observed in

many sporadic ALS patients. These RNA species are thought to have a dominant-negative effect, thereby suppressing EAAT2 protein expression [117]. However, it has been shown more recently that aberrantly processed mRNAs are also present in healthy individuals [118]. More recent work has identified a link to a mutation of the superoxide dismutase gene (*SOD1*), which is present in about 20% of ALS cases [3]. In transgenic mice with the mutant *SOD1* gene, EAAT2 expression is reduced by more than 90%, and the mice gradually develop hind-limb paralysis similar to that observed in the human disease. The mutant form of *SOD1* induces oxidative damage to the EAAT2 protein, suggesting that loss of EAAT2 in ALS could be due to oxidative conditions [116].

Although altered glutamate transporter expression has been associated with a number of neurological diseases and injuries, it is still unclear in many cases whether this change is a causative factor or a compensatory mechanism in response to increased glutamate levels. In stroke and ischemic/hypoxic brain injury, there is substantial evidence for a compensatory mechanism. A number of animal models of stroke have demonstrated that glutamate transporter expression increases following ischemia and hypoxia, suggesting that the expression of these transporters is altered in order to compensate for pathological conditions [119]. Also supporting this theory, brain damage in response to induced ischemia was exacerbated in mice expressing reduced GLT1 protein levels [120, 121]. However, several accounts conflict with these studies, instead reporting decreased glutamate transporter expression following ischemia [116].

In AD, the expression and function of EAAT1 and EAAT2 are altered. In postmortem studies of AD brains, reduced levels of EAAT2 were observed in frontal cortex [122]. This reduced expression was correlated with the presence of amyloid (A β) plaques, one of the trademark signs of AD. It has been suggested that the A β protein leads to glutamate toxicity by directly affecting glutamate transporter function. One possible mechanism is that A β instigates transporter reversal, thereby increasing extracellular glutamate to excitotoxic levels. Another possibility is that A β leads to the oxidation of the glutamate transporter and impedes transporter function, as in the *SOD1* mutant model of ALS [117].

Other disorders, such as Parkinson's disease (PD), have been shown to affect multiple neurotransmitter systems. While PD leads to the specific degeneration of dopaminergic neurons in the basal ganglia, glutamate as well as dopamine neurotransmission plays an important role in the disease. Compounds that alter glutamate transmission ameliorate parkinsonian symptoms in animal models of the disease [123, 124]. However, studies of glutamate levels in animal models of PD are inconclusive, with some studies reporting increased striatal glutamate concentrations and others showing no change. 3,4-Dihydroxyphenylalanine (L-DOPA) a common therapeutic approach in PD, has been shown to increase extracellular glutamate concentrations and glutamate transporter (GLT1) expression in the basal ganglia [125].

16.2.2 Plasma Membrane Monoamine Transporters

As described above, the plasma membrane transporters for dopamine, norepinephrine, and serotonin are targets for a number of clinical drugs and drugs of abuse. In addition, postmortem analysis and live imaging studies have established that changes in monoamine transporter expression are associated with several brain disorders.

Recently, specific gene polymorphisms for these transporters have been associated with increased risk of developing certain neurological disorders. These genes are currently being investigated for their capacity to cause changes in protein function or expression that may underlie disease.

16.2.2.1 Serotonin Transporters. SERT has been associated with affective disorders such as anxiety and depression as well as autism, substance abuse, and gastrointestinal disorders. The role of the serotonergic system in depression is well documented, with depressed patients exhibiting decreased plasma levels of serotonin as well as CNS changes in 5-HT receptors and transporters [126]. The class of antidepressants known as selective serotonin reuptake inhibitors (SSRIs) acts at SERT to prevent neurotransmitter reuptake and thereby increase extracellular 5-HT levels. The effectiveness of these antidepressants led researchers to question whether SERT dysfunction could be responsible for the decreased 5-HT levels observed in depression and other affective disorders. Supporting this idea, SERT is reportedly decreased in postmortem brain tissue from depressed patients [127]. Recent imaging studies in living subjects have reported a decrease in SERT availability in depressed subjects, although some studies have produced contradictory results [128, 129]. Additionally, two polymorphisms of the *SERT* gene are linked to increased likelihood of depression in humans; a variable number of tandem repeats (VNTR) located in intron 2 (5-HTT-VNTR) and a deletion/insertion in the promoter region (5-HTTLPR) [126, 130]. However, SERT polymorphisms are too rare to explain the prevalence of depression, and further research will be needed to establish the interaction of altered SERT expression and function with the other factors involved in depression and other mood disorders.

Several other affective disorders are linked to polymorphisms of the *SERT* gene. An uncommon single-substitution mutation of the *SERT* gene, *I425 V*, has been shown to contribute to autism, anorexia, Asperger's syndrome, and a familial form of obsessive compulsive disorder (OCD) [131]. This substitution leads to increased SERT function, thereby chronically reducing extracellular 5-HT levels [132]. Other alleles of the 5-HTT-VNTR polymorphism are associated with bipolar disorder and schizophrenia, although results vary across ethnic groups [133, 134]. We will discuss these monoamine transporter polymorphisms in more detail below.

5-HT is also found in peripheral systems, including platelets, the pulmonary endothelium, the placenta, and the gastrointestinal (GI) tract. It is released from gut endochromaffin cells to regulate fluid secretion and gut motility. Serotonin transporters are present on neurons and endothelial cells of the gut, where they prevent receptor desensitization by regulating extracellular 5-HT levels. SERT knockout mice exhibit impaired GI function. This may correspond to the GI problems that often accompany anxiety disorders and antidepressant treatments in humans [135]. SERT dysfunction could therefore be expected to lead to GI disorders. In agreement with this premise, the 5-HTTLPR is associated with increased instances of irritable bowel syndrome (IBS) [136]. In addition, SERT knockout mice show impaired GI motility [137]. However, as in the neurological disorders associated with SERT polymorphisms, IBS is influenced by a number of factors, and the importance of a single gene polymorphism among these factors is difficult to quantify.

16.2.2.2 Dopamine Transporters. The DAT is linked to PD, Tourette's syndrome, attention-deficit hyperactivity disorder (ADHD), and substance abuse. In all of these disorders, expression of DAT is altered, with decreases reported in PD, while ADHD and Tourette's disorder are characterized by increases in transporter density [138].

As in many disorders involving monoaminergic systems, ADHD seems to be regulated by multiple genetic and environmental factors. Both noradrenergic and dopaminergic systems appear to be affected in ADHD, as evidenced by the fact that stimulants used in ADHD treatment target DAT and NET [139]. Increased risk of ADHD is associated with a number of genes, including those for DAT, NET, and SERT [140]. In individuals with ADHD, increased expression of DAT has been observed [138, 141]. In a small subset of ADHD patients, a VNTR polymorphism of DAT appears to result in increased DAT expression in humans. Although this polymorphism is observed in only a small number of ADHD individuals, single-photon-emission computed tomography (SPECT) imaging shows substantially elevated DAT levels in these subjects [138]. Another line of research concerns the DAT knockout mouse, which has become an important animal model of ADHD. Like ADHD patients, DAT knockout mice show increased spontaneous activity and cognitive deficits and are calmed rather than excited by psychostimulants, an abnormality specific to ADHD [142]. However, in the mutant mice, overactivity is observed in novel situations but not in their home cage, whereas children with ADHD are generally quieter when exposed to new situations and more active in situations in which they are accustomed [141].

DAT plays an important role in PD, which is characterized by the death of dopaminergic neurons in the substantia nigra. This association was discovered when MPP⁺ (derived from MPTP) was shown to specifically poison dopaminergic cells after being taken up by DAT, reproducing the symptoms of PD [143]. This has led to speculation that environmental toxins could trigger PD via a similar mechanism [144]. Support for this theory comes from epidemiological studies showing a link between exposure to certain pesticides or other environmental toxins and the development of PD [145]. Thus far, genetic studies of the *DAT* gene show little association with PD [146].

16.2.2.3 Norepinephrine Transporters. Orthostatic intolerance is an autonomic system disorder that results in dizziness, syncope, fatigue, disordered thought, and postural tachycardia. Patients with this genetic disorder show plasma norepinephrine concentrations that are significantly elevated, and this raises the possibility that orthostatic intolerance is a deficit in NET clearance. Genetic analysis of the *NET* gene in these patients revealed a coding mutation that converts an alanine residue to proline in a TMD. Expression of a mutant NET protein carrying the proline site in transfected cells revealed a transporter with function that was less than 5% of wild type [147, 148]. This analysis revealed the first coding sequence mutant in a transporter associated with a disease state. More recently, it has been shown that this mutation not only disrupts the surface expression of the mutant but in coexpression with wild-type NET also prevents wild-type NET from trafficking normally [149].

16.2.3 Plasma Membrane GABA Transporters

Despite abundant physiological data to suggest that GABA transporters regulate GABAergic neurotransmission and the long practice of using GAT antagonists in the

treatment of epilepsy, the pathological link between these transporters and human diseases is not well established. This missing link is partly due to the complicated role that GABA transporters play in human diseases; GABA transporter deficiencies increase the susceptibility to hyperexcitability and thus may contribute to risk factors rather than directly causing symptoms.

GAT1 antagonists (i.e., tiagabine and NNC-711) [150–152] and glial (possibly GAT3-mediated) and other GABA uptake inhibitors (i.e., SNAP-5114, NNC 05-2045, and *N*-methyl-exo-THPO) [153–156] have neuroprotective and anticonvulsant effects. These are primarily mediated by elevating the ambient extracellular GABA concentrations.

Changes in GAT1 expression level are related to various neurological disorders. Upregulation of neocortical GAT expression is associated with seizure activity. In rat neocortex, hormone-induced seizures lead to an increase in GAT1-expressing interneurons [157] and a transient increase in GAT3 mRNA (but not protein) expression in seizure-induced rats 1 h after the last seizure [158]. Transgenic mice overexpressing GAT1 exhibit increased susceptibility to chemically induced seizures, although they do not display spontaneous seizure activity [159]. On the other hand, reduced GAT expression has been observed in the cortex of rat epilepsy models [160], in the neocortex of genetically epilepsy-prone rats [161], in the sensorimotor cortex of a rat pilocarpine model of temporal lobe epilepsy [162], and in the neocortex of patients with temporal lobe epilepsy and focal dysplasia [163]. This variation in GABA transporter regulation in epilepsy might reflect different pathophysiological mechanisms and temporal patterns of the disease states.

Following reports that the GABA uptake inhibitors tiagabine and NCC-711 exert neuroprotective effects, cortical expression of GAT1 and GAT3 was investigated in a rat model of transient focal ischemia [164]. Unlike GAT1, the expression of GAT3 was dramatically changed during this process. Neurons, including pyramidal neurons, became immunoreactive for GAT3. The novel reactivity of GAT3 at postsynaptic sites may increase GABA uptake, effectively reducing the amount of GABA available for binding to receptors and thus increasing neuronal excitability [164, 165].

16.2.4 Plasma Membrane Glycine Transporters

GlyT-deficient mice show phenotypes mimicking the symptoms of several human diseases. Newborn mice deficient in GlyT1 are anatomically normal but show severe motor and respiratory deficits and die within a day after birth [46, 47]. The deficits in GlyT1-deficient mice mimic glycine encephalopathy (also called nonketotic hyperglycinemia), a life-threatening disorder in neonates characterized by increased glycine levels in blood and cerebrospinal fluid accompanied by lethargy, hypotonia, and hyporesponsivity. Many patients become mentally retarded and/or develop seizures. Mice deficient in GlyT2 are normal at birth but during the second postnatal week develop a lethal neuromotor deficiency that resembles severe forms of human hyperreflexia (hereditary startle disease) and is characterized by spasticity, tremor, and an inability to right themselves [46, 47]. Although neither of the human glycine transporter genes has been linked to nonketotic hyperglycinemia or hyperreflexia, mutations in glycine receptors [166] and enzymes responsible for degrading glycine [167] have been implicated. It will be interesting to see whether dysfunctional glycine transporters also play a role in a subset of these conditions.

Since glycine is also known to act as a coagonist of excitatory NMDA receptors, it has been hypothesized that GlyT1 can influence excitatory synaptic signaling by regulating ambient glycine concentrations [45, 168, 169]. Placebo-controlled clinical trials with agents that directly or indirectly activate the glycine modulatory site consistently reduce negative symptoms and frequently improve cognition in patients with chronic schizophrenia who are receiving concurrent typical antipsychotics. Thus glycine transporters may be an important therapeutic target for the treatment of schizophrenia.

16.2.5 Vesicular Transporters

Thus far, only a few associations between vesicular transporters and disease have been described. VGLUT1 expression is decreased in the hippocampi of patients with schizophrenia [170]. It has also been proposed that the vesicular monoamine transporter (VMAT2) contributes to diseases of monoaminergic systems, including affective disorders, schizophrenia, PD, and other neuropsychiatric disorders. One piece of evidence for this idea is the finding that VMAT2 expression is decreased by exposure to clozapine, an antipsychotic drug that acts at serotonin receptors [171]. Vesicular transporters are likely to be important targets for therapeutic drugs. For instance, lobeline, a drug widely used as an emetic and to assist in smoking cessation, specifically targets VMAT2 and affects dopamine storage and release [172]. VMAT2 has also been targeted as a potential for gene therapy in PD [173].

16.2.6 Interactions Between Neurotransmitter Systems

Finally, many diseases involve multiple neurotransmitter systems and are influenced by a variety of genetic and environmental factors. A good example for this is schizophrenia, which is attributed in part to the dysfunction of dopaminergic systems. Dopamine release in this system is modulated by a number of neurotransmitters, including GABA, glutamate, acetylcholine, serotonin, and norepinephrine [174]. Accordingly, the prefrontal glutamatergic and GABAergic systems, including EAATs and GATs, have both been shown to undergo changes in schizophrenia. In fact, one hypothesis asserts that schizophrenia is caused not by dopaminergic problems but by dysfunction of cortical or subcortical glutamatergic transmission [175]. Altered glutamate transmission may be due to changes in VGLUTs or by altered levels of inhibitory transmitters [176]. A polymorphism of the *SERT* gene is also associated with greater risk of schizophrenia [134]. However, whether or not changes in various transporters are an underlying risk factor for schizophrenia, these transporters are currently being studied for their potential as targets of therapeutic drugs. For example, several new antipsychotic medications target the glycine transporter to inhibit uptake and thereby increase the amount of ambient inhibitory neurotransmitter [177]. The glutamate transporter has also been suggested as a possible target for drug intervention [178]. Because of the complicated modulation of dopamine neurotransmission, it is difficult to isolate any one of these systems as the cause of schizophrenia. However, the multiplicity of factors that contribute to dopaminergic transmission allow for a wide variety of therapeutic targets to be explored.

16.3 PLASMA MEMBRANE NEUROTRANSMITTER TRANSPORTER REGULATION

If fine tuning of phasic and tonic levels of neurotransmitter is crucial for normal cell signaling, then it is not surprising that the brain has developed mechanisms for fine tuning transporter action to achieve this goal. Changes in the activity or expression of transporters will have a significant impact on the amount of transmitter being released, the amount that reaches neurotransmitter receptors, how distant the transmitter can travel from its release site, and how long it remains extracellularly before it is sequestered. These changes, in turn, will influence pre- and postsynaptic responses during neurotransmission. In fact, endogenous mechanisms such as neural activity, hormones, growth factors, second-messenger systems, and posttranslational protein modifications regulate transporter expression and transport rates both acutely and chronically. These forms of regulation are, in general, likely to be homeostatic responses to sustain normal signaling; however, transporter dysregulation may impact several pathophysiological states as well. In the end, understanding the mechanisms by which transporters are regulated may provide insights into therapeutic approaches that target transporters. A complete examination of chronic and acute regulation of transporters is beyond the scope of this chapter. Instead, two examples of regulation will be examined in detail: chronic regulation of plasma membrane monoamine transporters and acute regulation of plasma membrane GABA transporters.

16.3.1 Chronic Regulation

16.3.1.1 Polymorphisms. Genetic polymorphisms in human transporter genes indicate individual mosaics in transporter expression level, cellular localization, uptake activity, and so on. Frequent linkages and associations of transporter polymorphisms with human diseases are discussed in the previous section. To understand how human transporter genes are organized and how their functions are regulated by polymorphisms is therefore of special interest from a clinical standpoint. Transporter gene polymorphisms include SNPs (single-nucleotide polymorphisms), polymorphisms in regulatory regions, VNTRs, Taq1 polymorphisms, variant splicing forms, and others.

16.3.1.1.1 Single-Nucleotide Polymorphisms. A site is considered polymorphic if the frequency of the observed allele is $> 1\%$ in human populations, while rare changes are termed mutations. Sequencing efforts have discovered at least 28 nonsynonymous coding SNPs in monoamine transporters (13 in NET, 5 in DAT, and 10 in SERT). In addition, synonymous coding SNPs, SNPs in introns, and SNPs in flanking regions have been found and have been deposited in the Single Nucleotide Polymorphism database at the National Center for Biotechnology Information (NCBI) (dbSNP) at <http://www.ncbi.nlm.nih.gov/SNP>. SNPs in noncoding regions do not directly affect the amino acid sequence of transporter proteins but may nonetheless contribute to transporter function alteration by changing their transcriptional and translational properties or by altering the targeting or trafficking of transporter proteins to appropriate cellular organelles. As mentioned in the previous section, one of the

SERT polymorphisms (I425 V) has been examined in detail and found to be a gain-of-function mutation that is refractory to regulation by protein kinase G [132].

16.3.1.1.2 Polymorphisms in Promoter Regions. Two polymorphic regions have been identified in human *SERT* gene promoter: 5'-HTTLPR and 5'-HTTSPR (long promoter region and short promoter region). The difference between these two variants is 44 bp, which is significant enough to induce a twofold serotonin uptake by the SERT with LPR [179]. Individuals with two short alleles, which are associated with decreased SERT expression, have a greater risk of anxiety, mood disorders, alcohol abuse, and various neuropsychiatric disorders, suggesting that such genetic regulation may contribute to disease [130].

16.3.1.1.3 Variable Number of Tandem Repeats. VNTR polymorphisms have been identified in monoamine transporter genes in introns such as the 3' untranslated region. As mentioned above, alleles of the 5-HTT-VNTR polymorphism are associated with bipolar disorder and schizophrenia, although results are different in specific ethnic groups [133, 134]. It is hypothesized that different numbers of copies of the repeat sequence might regulate the transporter function by affecting the mRNA stability, targeting properties, and translation efficiency.

16.3.1.1.4 Variant Splicing Forms. Primary transcripts from genomic DNA have splicing junctions where introns are excised and exons are connected to make coding DNA. By excising at different splicing sites, different coding DNA sequences may be generated from the same genomic DNA. Such regulation has been found in transporters and directly affects the transporter protein structure. For example, an alternatively spliced mRNA product of hNET having an additional leader sequence shows strong tissue-specific enhancement of transcriptional activity of the gene, thus increasing hNET expression [180]. Splice variants in the 3' region, which lacks certain protein-protein interaction sites, may result in the targeting of the protein to inappropriate cellular locations [181].

16.3.1.2 Multiple Transcription Initiation Sites. A number of canonical transcription binding sites found in the promoter region of SERT may be important in controlling the responses of transporter genes to regulatory factors. For example, a TATA-like motif, an AP1 site, a CREB binding element, AP2, NF-IL6, NF- κ B, and SP1 sites have been identified in the SERT promoter region [182]. The actual cellular signaling pathways responsible for initiating regulation are largely unknown.

16.3.1.3 Glycosylation. The large extracellular loop between TMDs 3 and 4 of plasma membrane neurotransmitter transporters contains consensus sites for post-translational glycosylation. In SERT, the absence of sugar moieties decreases the surface expression of the transporter without effect on steps related to 5-HT translocation [183]. The same is true for NET [184]. The loss in NET expression is correlated with a decrease in protein stability and half-life; however, these alterations do not account for all of the decrease in function in these mutants [62]. In DAT, glycosylation mutants are not excluded from insertion to the plasma membrane, but their time on the plasma membrane is significantly reduced [185].

Two more recent studies link glycosylation to two other aspects of monoamine transporter behavior. SERT is an oligomer [186], and in SERT mutants that are refractory for glycosyl modification, SERT monomers do not form oligomeric complexes. In addition, protein–protein interactions between SERT and myosin IIA are disrupted in these glycosylation mutants, which may affect the ability of SERT to be regulated by protein kinase G [187]. In NET, chronic exposure of the transporter to high levels of norepinephrine reduces the fraction of NET that is glycosylated. This downregulation in NET function may be associated with congestive heart failure [188].

16.3.1.4 Chronic Substrate Treatment. Since monoamine transporters are the sites of action of many clinically relevant drugs, some of which act as transportable substrates and others that are transporter antagonists, there has been much interest in the long-term regulation of transporter function by these and related compounds. In general, the compounds examined in detail include nontransporter substrates that act to alter transmitter levels, neurotransmitter receptor agonists and antagonists, and transporter substrates. For a more complete examination of this topic, see [189].

Multiday administration of reserpine, an inhibitor of VMAT, decreases NET [190] and DAT expression [191], while monoamine oxidase inhibitors, which act to prolong monoamine lifetimes, increases expression of these two transporters. Inhibition of the enzyme necessary for dopamine and norepinephrine synthesis downregulates DAT expression in brain, while administration of the dopamine precursor L-DOPA upregulates DAT expression [192]. Although the effects of these drugs over time are complex, as a first approximation, these findings are consistent with a homeostatic mechanism underlying chronic monoamine transporter regulation: Increased transmitter results in increased transporter expression and decreased transmitter results in decreased transporter expression. Consistent with this is the finding that activation of presynaptic adrenergic autoreceptors with clonidine, which downregulates norepinephrine release, reduces NET expression [193].

Less clear in terms of chronic regulation are the effects of drugs that target monoamine transporters directly. Some of this ambiguity is likely due to experimental systems being employed and the time course over which the experiments were performed. In animals treated with rather specific NET inhibitors, NET expression was either reduced [194] in some brain regions or not reduced at all [86]. In expression systems, the nonspecific antagonist and the nonspecific transportable substrate amphetamine also reduced NET expression [195]. For DAT, there is little consistent evidence for chronic regulation by DAT-specific substrates, cocaine or amphetamine; however, there is some evidence for short-term changes in expression during withdrawal from these compounds [189].

For SERT, there has been much interest in the long-term effects of SSRIs on transporter expression. In vivo, treatment of rats for three weeks with SSRIs results in a 50–80% reduction in SERT binding in multiple brain areas; this reduction is not due to a change in the number of 5-HT neurons [196]. In cultures of thalamocortical neurons that transiently express SERT, multiday treatment with SERT antagonists such as fluoxetine (Prozac) and cocaine reduce total SERT levels and the time course over which SERT is expressed. 5-HT and MDMA have the opposite effect [197]. Taken together, these studies again support the idea that cells regulate monoamine transporter expression in response to perceived transmitter levels. Since transporter

antagonists reduce transporter levels even in the presence of high extracellular levels of transmitter, this suggests that transporter activity may be in part the monitor that cells are using to determine how to adjust transporter levels.

16.3.2 Acute Regulation

Acute modulators regulate transporter function by changing both transport activity and/or transporter surface expression on a time scale of minutes. Over the past decade, significant progress has been made in defining the initiators of the regulation, the subcellular pathways that induce the regulation, and the mechanisms by which transporter function and expression are altered. While the majority of research in this field has been done on plasma membrane transporters of the SLC1 and SLC6 families, all transporters are subject to acute regulation. Readers are referred to a number of thorough examinations on this subject [189, 198–202]. Below, we give an example of the multiple forms of regulation by examining acute modulation of the plasma membrane GABA transporter GAT1.

16.3.2.1 Second Messengers. GAT1's primary sequence contains multiple consensus phosphorylation sites on serine and threonine residues [32]. Initial experiments [203] showed that drugs which alter PKC levels affect GABA uptake on a time scale of minutes. The magnitude and direction of PKC regulation are cell-type dependent [204, 205], but in neurons, PKC activation is correlated with a decrease in surface GAT1 expression and this change in transporter levels correlates well with changes in GABA uptake [206]. Indeed, PKC-mediated alterations in the subcellular distribution of transporter protein are a hallmark of all plasma membrane neurotransmitter transporters. Changes in surface expression could be due either to changing the rate of delivery of transporters to the cell surface, changing its rate of removal from the cell surface, or both. For GAT1, basal recycling rates are on the time scale of minutes. In the presence of PKC activators, the endocytosis rate increases twofold; the exocytosis rate is unaffected [34]. At least part of PKC's action on GAT1 is via direct phosphorylation of serine residues [207].

In neurons that endogenously express GAT1, tyrosine kinase (TRK) inhibitors decrease GABA uptake and tyrosine phosphatase inhibitors have the opposite effect. The decrease in uptake correlates with a decrease in direct tyrosine phosphorylation of GAT1 and results in a redistribution of the transporter from the cell surface to intracellular locations. Tyrosine residues in GAT1's first and third intracellular loops can be phosphorylated and are responsible for the regulation of GAT1 trafficking [208]. As with PKC, tyrosine kinase phosphorylation influences the rate of GAT1 internalization, but in the opposite direction. Interestingly, the relative levels of serine phosphorylation and tyrosine phosphorylation are negatively correlated. The data support the idea that GAT1 exists in either of two mutually exclusive phosphorylation states and that the relative abundance of these states determines in part the relative subcellular distribution of GAT1 [207].

In brain, these kinase pathways are likely activated by cell surface receptors. Specific agonists of G-protein-coupled receptors for acetylcholine, glutamate, and serotonin all downregulate GAT1 function [209]. This inhibition is mimicked by PKC activators and prevented by specific receptor antagonists and PKC inhibitors. TRK receptors, such as the receptors for nerve growth factor and brain-derived

neurotrophic factor (BDNF), induce tyrosine kinase activity. BDNF upregulates GAT1 function, and this increase correlates with an increase surface transporter expression [210].

A hallmark of neurotransmitter release is calcium- and depolarization-dependent exocytosis. This is also true of GAT1 [211]. In the presence of extracellular Ca^{2+} and depolarization, the amount of surface GAT1 increases. This increase is prevented in the absence of extracellular Ca^{2+} or in the presence of the Cd^{2+} , which blocks voltage-gated calcium channels. This suggests that many of the same factors that regulate transmitter release are also likely to regulate transporter expression.

16.3.2.2 Agonists and Antagonists. As discussed in the section on chronic regulation, if cells regulate transporter expression in order to control extracellular transmitter levels, then the most direct route would be to have the transporter directly sense transmitter levels and regulate its expression. Specific GAT1 substrates upregulate transport; GAT1 transport inhibitors that are not transporter substrates downregulate transport. Increases in transport are correlated with an increase in surface transporter expression, which results from a slowing of GAT1 internalization [212]. Incubation of GAT1-expressing neurons with transporter ligands alters the amount of GAT1 that is tyrosine phosphorylated, suggesting a model in which substrates permit the phosphorylation of GAT1 on tyrosine residues and that the phosphorylated state of the transporter inhibits transporter internalization [208].

16.3.2.3 Interacting Proteins. The ability to regulate transporter trafficking suggests that the machinery involved in trafficking will interact with transporters. Overexpression of the plasma membrane SNARE proteins [213, 214] syntaxin 1A or SNAP-25 alters the subcellular distribution of GAT1 [201] and toxins that specifically inactivate these proteins regulate GAT1 endogenously in neurons [215]. Syntaxin 1A acts as a positive regulator of GAT1 surface expression. Immunoprecipitation experiments reveal a physical interaction between GAT1 and syntaxin 1A [206] and the association of GAT1 with syntaxin 1A is mediated predominantly by amino acids 30–54 in GAT1's N-terminal cytoplasmic tail [216]. Syntaxin-1A-regulated trafficking effects are also seen for GlyT [217], NET [218], and SERT [219, 220].

Regulating transporter trafficking represents one method for modulating extracellular transmitter levels and cell signaling. Another way is to directly alter rates of transmitter transport. Measurements of flux rates show that syntaxin 1A reduces GABA transport from seven to approximately two molecules per second [216]. Application of transporter substrates increases the flux rate through GAT1, essentially reversing syntaxin 1A inhibition [221]. The substrate-induced rate change requires the presence of syntaxin 1A, and in neurons that endogenously express GAT1 and syntaxin 1A, substrate application decreases the fraction of syntaxin 1A that is bound to GAT1 on a time scale comparable to the substrate-induced change in flux rates. These data suggest that substrate translocation regulates GAT1–syntaxin 1A interactions and provide a mechanism by which GABA transport can be increased during times of rising synaptic GABA concentrations. Furthermore, these and other data suggest that many of the processes involved in transporter regulation interact to ultimately determine transporter function and ultimately neural function.

17.1 INTRODUCTION

Nitric oxide (NO) is one of the major components of air pollution related to modern human activities. In biological systems, NO was first described as an endothelium-derived relaxing factor (EDRF) because of its action on relaxing smooth muscle in blood vessels. Soon it was found that NO can regulate pathways ranging from hormonal control in plants to blood circulation and neurotransmission in mammals. In tissues, endogenous NO is synthesized by nitric oxide synthases (NOSs) that

convert L-arginine to NO and L-citrulline [1]. There are at least three classes of NOS in animals—neuronal NOS (nNOS), inducible NOS (iNOS), and endothelial NOS (eNOS)—and they are responsible for producing NO in different tissues (Fig. 17.1). Nitric oxide synthases produce NO by oxidizing L-arginine to L-citrulline and NO with the use of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and oxygen (Fig. 17.2). NO is an important signaling molecule that can control a variety of processes, and in fact many pharmacological targets are aimed at the NO signaling pathways. One of the best examples is nitroglycerin. Nitroglycerin has been used as a therapeutic agent for relieving symptoms of cardiovascular diseases for more than a century, even before NO was identified as the EDRF in the 1980s. Another gas molecule that is emerging as a signaling agent is carbon monoxide (CO). It has also been suggested that NO and CO might coordinate together to mediate different signal transductions [2]. The in-depth understanding of the molecular signaling mechanisms of these gaseous signaling molecules should provide valuable information in the development of new pharmacological targets for different diseases.

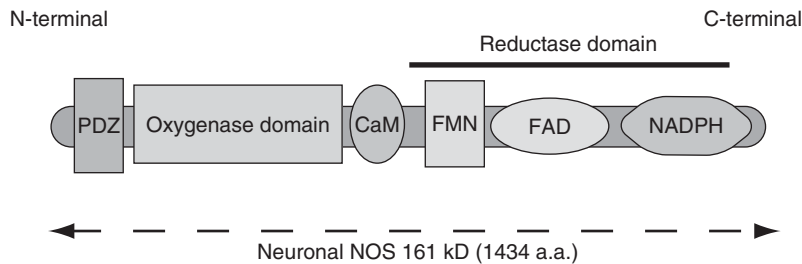

Figure 17.1 Structural domains of neuronal nNOS. The enzyme is made up of 1434 amino acids with several conserved domains. nNOS contains a post-synaptic density protein (PSD95), a Drosophila large tumor suppressor (DlgA) and azol (PDZ) domain, an oxygenase domain, a calmodulin binding domain (CaM), and a reductase domain. Within the reductase domain, there are conserved domains that can bind to flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), and NADPH. Both eNOS and iNOS consist of a similar domain structure except for the absence of the PDZ domain. (See color insert.)

Figure 17.2 NOS converts L-arginine to L-citrulline and NO in the presence of NADPH and oxygen.

17.2 PHYSIOLOGICAL ROLE OF NO

Since the discovery of NO as an important signaling molecule, a number of physiological functions were found to be modulated by NO. The most well known effect of NO is its blood vessel dilating activity. NO originating from endothelium was first described as an EDRF because of its action on relaxing smooth muscle in blood vessels. NO from the endothelium is produced by eNOS in response to different stimuli such as shear force generated from blood flow. The NO generated from the endothelium can then diffuse to the smooth muscle of blood vessels and activate soluble guanylate cyclases (GCs) to produce cyclic guanosine monophosphate (cGMP), which can subsequently induce vessel dilation. eNOS knockout mice suffer from consistent hypertension, which supports the importance of eNOS in the regulation of the vascular system [3]. In the central nervous system, NO functions as a neurotransmission modulator. For instance, the PDZ domain of nNOS is linked to the *N*-methyl-D-aspartic acid (NMDA) receptor through postsynaptic density protein 95 (PSD95) where it modulates NMDA receptor neurotransmission [3]. In the immune system, macrophages use NO produced by iNOS to kill microbes. The activation of iNOS during the inflammatory response is also responsible for NO-induced tissue injuries in the autoimmune diseases, such as multiple sclerosis (MS) [4]. Excessive production of NO in the brain promotes neuronal toxicity under unfavorable conditions. For example, during cerebral ischemia increased stimulation of excitatory neurotransmitter glutamate receptors will result in the influx of Ca^{2+} and activation of nNOS to increase the production of NO [5]. The high levels of NO can in turn react with reactive oxygen species to form the highly toxic peroxynitrite and promote neuronal cell death [5]. Interestingly, in ischemic preconditioning, NO activates p21Ras, which can promote neuronal survival against subsequent major ischemic challenge [6]. Some of the mechanisms of how NO can mediate such a diverse spectrum of physiological functions is still not fully understood. However, it is emerging that nitrosylation of metal or cysteine residues in proteins might represent one of the major mechanisms of how NO can achieve its role in signal transduction in different systems.

17.3 NITROSYLATION AS SIGNALING MECHANISM OF NO

NO is a highly reactive free-radical molecule that has an unpaired electron occupying an antibonding π orbital [7, 8]. The unique chemical properties of NO facilitate its role as an important signaling molecule in biological systems. NO can mediate its effect by reacting with biological molecules directly or through the help of other reactive oxygen species [8] (Fig. 17.3). For instance, NO reacts with ferrous ion containing heme complexes such as in guanylate cyclase (GC), P450, and in hemoglobin to form an iron nitrosyl complex in that mediates functional changes in these proteins [8, 9]. The activation of GC by NO is a good example of how NO functions as a signaling molecule through the direct modification of biological molecules. Guanylate cyclases are enzymes that convert guanosine triphosphate (GTP) to cGMP [10]. NO activates GC to increase cGMP levels [10]. In the basal and inactivated state of GC, the heme iron and the axial ligand formed from the histidine residue in the enzyme prevent the active site of GC from being easily accessible by

Figure 17.3 Schematic diagram showing how NO can react with different biological molecules to mediate its effect. NO produced from NOS can activate directly sGC to promote vasodilation in blood vessels via increasing production of cGMP. NO can S-nitrosylate cysteine residues in proteins to mediate its effect on signal transduction. NO can also react with superoxide anion and induce damage on various cellular components. (See color insert.)

substrate [10]. NO activates GC by binding to the heme group in GC, which results in a conformational change of the enzyme making the active site more available to its substrate [10]. The increased production of cGMP from GC can then activate different effectors to mediate cellular responses such as vasodilatation in blood vessels.

Oxygen and other free radicals can also react with NO to form reactive nitrogen oxide species and to exert its effects on different biological molecules [7–9]. For example, superoxide anion can react with NO to form peroxynitrite. Highly reactive peroxynitrite can then damage protein by reacting with the tyrosine residues to form 3-nitrotyrosine, induce lipid peroxidation, and cause DNA damage. Another major signaling mechanism of NO is the formation of nitrosothiols through the process of nitrosylation. Nitrosylation refers to the attachment of a NO molecule to a metal ion or cysteine residue in proteins. The reaction is reversible and needs to be distinguished from nitration, which refers to the introduction of a NO_2 group to a tyrosine or tryptophan residue in protein. An increasing number of proteins are modified by NO through nitrosylation, and the modification is viewed as an important redox sensing and/or signaling mechanism that may be comparable to phosphorylation [11]. One of the characteristics of nitrosylation is its reversibility and the dependence of a specific acid–base motif in the protein structure [12, 13]. The initial discovery of the acid–basic motif requirement was based on the comparison of primary sequences of known nitrosylated proteins. It was soon found that cysteine residues that are preceded by an acidic amino acid and then followed by a basic amino acid have a

significant higher probability for being modified by NO through *S*-nitrosylation. However, it was later observed that the acid–base motif is not necessarily constrained to a primary sequence. For example, cysteine residues 221 and 273 in dimethylargininase-1 (DDAH-1) has been shown to be modified by NO through *S* nitrosylation [14]. Surprisingly, it was found that no acid–base motifs are flanking the primary sequence of these cysteine residues [14]. With a more detailed three-dimensional structural simulation analysis, it was found that these cysteine residues are actually surrounded by acidic and basic amino acids that are brought together by the tertiary structure and can therefore form the acid–base motifs to facilitate the process of *S* nitrosylation [14].

The mechanisms of how proteins are nitrosylated and denitrosylated are not well characterized. It has been speculated that *S*-nitrosylation might require actions of certain enzymes to facilitate the process, but so far only metabolism of *S*-nitrosoglutathione (GSNO) to *S*-nitrosocysteinyl glycine (CGSNO) by γ -glutamyl transpeptidase (γ -GT) is found to facilitate the process of nitrosylation [15]. In general, the formation of nitrosothiols is believed to involve the reaction of NO and O₂ to form the N₂O₃ as a first step that can subsequently react with thiol groups in proteins to form the resultant nitrosothiols [11]. The metabolism of nitrosothiols is also not fully understood. Components in cells are known to be able to metabolize nitrosothiols, and at least one enzyme, glutathione-dependent formaldehyde dehydrogenase (GS-FDH), has been identified to have high affinity to metabolize GSNO. GS-FDH is highly conserved from bacteria to humans and the enzyme is now referred to as *S*-nitrosoglutathione reductase (GSNOR) [16]. Since GSNO is regarded as the reservoir of nitrosothiols, regulation of its levels by GSNOR might represent an important metabolic control of nitrosylation in proteins [15, 16]. It is interesting that GSNOR only has high affinity to GSNO; other nitrosothiols such as *S*-nitrosocysteine or *S*-nitrosohomocysteine, are not affected by this enzyme, which suggests that other enzymes might also contribute to the overall metabolism of nitrosothiols [16].

17.4 DETECTION OF NITROSOTHIOLS

A number of methods are available to detect *S*-nitrosylation, but they both have their advantages and disadvantages [11]. Therefore a number of methods are usually employed to study *S*-nitrosylation.

The detection of nitrosothiols by chemiluminescence is one of the most sensitive approaches to measure *S*-nitrosylation. It was first developed to measure nitrosothiols in plasma [17] and later found to be able to distinguish different derivatives of NO species [18]. Generally, the basic idea is to release NO from nitrosothiols by ultraviolet (UV) radiation or chemical methods. The released NO is then reacted with ozone and the resultant chemiluminescence signal is measured. Despite the sensitivity, this method requires substantial investment of instruments and is usually not available in most laboratories.

Electrospray ionization mass spectrometry (ESI-MS) has been used with success in studies to detect *S*-nitrosylation in some proteins [14, 19, 20]. Apart from being able to detect *S*-nitrosylation in protein, ESI-MS can also provide stoichiometric information regarding the modification. Usually, a purified protein is exposed to an NO donor and the resultant *S*-nitrosylated species will be digested by trypsin and the

NO-modified peptide will be detected and identified by ESI-MS. Up to now, only ESI-MS has been proven to be able to detect *S*-nitrosylation *in vitro*; the more widely available matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) was found to destroy the modification during the process of ionization [19].

Colorimetric and fluorometric methods remain one of the most commonly used approaches to detect nitrosothiols [21–23]. These methods use metal ions such as Hg^{2+} or Cu^{2+} to release the NO from samples containing nitrosothiols. The released NO can subsequently react with chemical reagents to form a colored or fluorescent compound [24]. The colored or fluorescent compound can then be measured by a spectrophotometer to quantify the amount of nitrosothiols in the samples. These methods are simple to perform with common laboratory equipment. The fluorometric method is usually more sensitive than the colorimetric method, but both methods suffer from potential interference from protein or biological molecules in the samples [24].

A more versatile approach to label *S*-nitrosylated proteins with a biotin moiety [25], the so-called biotin-switch method, can be used to detect *S*-nitrosylation in both *in vitro* and *in vivo* conditions. Essentially, the method includes the initial blocking of free cysteines in a nitrosylated protein with methyl methanethiosulfonate (MMTS) and then NO is released from the S–NO group by ascorbate. The free cysteine generated is subsequently labeled with biotin by a reaction with *N*-[6-(Biotinamido)hexyl]-3'-(2'-pyridyldithio)propionamide (biotin-HPDP). The labeled protein can be purified by avidin agarose for Western blot analysis or proceed for proteomics analysis. Although this method has been proven to be effective in detecting a wide range of *S*-nitrosylated proteins *in vitro* and *in vivo*, the sensitivity of this method is not as robust compared with other methods. The biotin-switch method also cannot be used to quantify the amount of nitrosothiols in samples.

Antibodies that were raised in rabbits by using *S*-nitrosocysteine as an antigen have been used in immunohistochemistry or Western blotting to detect *S*-nitrosylated proteins with success [22, 26, 27]. Although it is a convenient method to detect nitrosothiols in biological tissues, the antibodies tend to cross react with unmodified cysteine residues in protein, and therefore multiple controls are usually required with the use of these antibodies. For example, treating the sample with Hg^{2+} to release the NO can be used as a negative control, and a positive control can be performed by treating samples with an NO donor such as GSNO.

17.5 EFFECTS OF NITROSYLATION IN CELLULAR PATHWAYS

17.5.1 Ion Channels

Both ryanodine and NMDA receptors (NMDARs) are known to be regulated by NO through *S*-nitrosylation. The ryanodine receptor is a calcium channel that is highly expressed in skeletal muscle and is responsible for the release of calcium from the sarcoplasmic reticulum during muscle contraction [28, 29]. Activity of the ryanodine receptor is sensitive to changes in O_2 tension. The *S*-nitrosylation of 6–8 out of 50 cysteine residues in the receptor is responsible for activation of the channel in response to changes in O_2 tension [28, 29]. At least five cysteine residues in NR1 and NR2A subunits of NMDARs are modified by NO through *S*-nitrosylation [13, 30].

Figure 17.4 Schematic illustration of NMDAR complex signaling regulated by NO through *S*-nitrosylation. Ca^{2+} influx from the activation of NMDAR promotes the production of NO from the nearby nNOS. NO can then activate downstream signaling cascades such as p21Ras, GC, and Dexras. NO can also inhibit the activity of NMDAR through *S*-nitrosylation, which serves as a negative-feedback mechanism for the receptor complex [13]. (See color insert.)

In particular, nitrosylation of cysteine residue 399 of NR2A significantly inhibits the activity of the receptor [30]. The organization of the NMDAR complex also facilitates the control of its activity through nitrosylation. Since, nNOS is linked to the NMDAR complex via the PDZ domain, Ca^{2+} influx resulting from the activation of the receptor can activate nNOS to produce NO. The increased NO production can then act through *S*-nitrosylation and provide a feedback mechanism for the NMDAR complex [30, 31] (Fig. 17.4). Other downstream signaling molecules proximate to the receptor such as p21Ras and Dexras can all be modulated by *S*-nitrosylation [25, 32, 33] (Fig. 17.4).

17.5.2 Protein–Protein Interactions and Nitrosylation

There is always an intense interest to understand the mechanism of how *S*-nitrosylation can mediate its effect. Apart from modulating the enzymatic activities through the *S*-nitrosylation of critical cysteine residues in the active sites, another

emerging mechanism is to interfere with or promote protein–protein interactions when proteins are *S*-nitrosylated. For instance, in eNOS, dimerization of the enzyme is required for its activation. Interestingly, *S*-nitrosylation of eNOS can selectively interfere with the dimerization of eNOS, which can function as a negative-feedback mechanism [34]. In Hdm2, a human homolog of Mdm2, nitrosylation of Cys77 selectively interferes with the binding of its substrate, p53 [35]. In a recent report, a modified yeast two-hybrid screening was used to screen for protein–protein interactions that is dependent on nitrosylation. In this screening, it was found that interaction of procaspase-3 with acid sphingomyelinase (ASM) and NOS are NO dependent [36]. The *S*-nitrosylation of procaspase-3 selectively enhances its interaction with ASM and the interaction seems to inhibit basal caspase activity [36]. The interaction between procaspase-3 and NOS is dependent on the enzymatic activities of NOS. This finding also explains why cells expressing NOS may be resistant to cell death stimuli such as tumor necrosis factor and cyclohexamide [36].

17.5.3 Gene Transcription

NO is known to be involved in signaling cascades required for gene transcription. One of the mechanisms is through the modulation of the transcription factors, hypoxia-inducible factor (HIF), p53, and nuclear factor kappa B (NF- κ B) [37]. For instance, a recent paper has revealed how NO can regulate the activity of NF- κ B [38]. Under normal conditions, NF- κ B is sequestered by inhibitory κ B (I κ B) to the cytoplasm, and this prevents it from entering into the nucleus to initiate transcription. When the pathway is activated, I κ B kinase (IKK) phosphorylates I κ B and promotes I κ B degradation through the ubiquitin pathway [39]. The downregulation of I κ B allows NF- κ B to translocate to the nucleus and activate gene transcriptions [39]. IKK is subject to redox regulation, but the mechanism is not clear. On the other hand, NO is known to have an inhibitory effect on the NF- κ B activated transcription, and it has long been suspected that NO might mediate this inhibition via IKK. In fact it was found that NO can inhibit the kinase activity of IKK through *S* nitrosylation of Cys-179 of the beta subunit of IKK, thus inhibiting the activation of NF- κ B [38].

The mechanism of how NO affects the HIF-1-mediated transcription is not fully understood, but NO promotes the accumulation of HIF-1 in the nucleus and hence activates HIF-1-induced gene transcriptions [40]. The complex control of HIF-1-induced gene transcription in response to hypoxia is regulated in part through ubiquitination. Under normal normoxic condition, HIF-1 is hydroxylated by prolyl hydroxylases (PHDs) so that HIF-1 can be targeted by ubiquitin E3 ligase, pVHL (von Hippel Lindau protein), for degradation through the ubiquitin proteasomal pathway [37, 40]. On the other hand, during hypoxia, low O₂ level prevents PHD from hydroxylating HIF-1, resulting in the accumulation of HIF-1 in the cytosol [37, 40]. This leads to the translocation of HIF-1 into the nucleus, promoting the transcription of hypoxia-responsive genes [37, 40]. More detailed study suggests that NO acts on PHD and attenuates its activity on HIF-1, which ultimately promotes the accumulation of HIF-1 in the nucleus [40]. The mechanism of how NO can inhibit PHD is not clear, but it is highly possible that such action is mediated through nitrosylation [37].

Apart from interfering indirectly with gene transcription pathways, *S*-nitrosylation has also been found to modify transcription factors directly. For instance, the binding of estrogen receptor (ER) to the estrogen-responsive elements (EREs) can be directly interfered by NO [41]. This interference has been shown to affect the ER-mediated gene transcription in cells [41]. NO appears to selectively *S*-nitrosylate cysteine residues that coordinate Zn^{2+} in the two major DNA binding domains of ER and hence directly prevent it from binding to EREs in the activation of ER-dependent gene transcriptions [41].

17.5.4 Vesicular Transport

Vesicular trafficking is a critical cellular process that regulates many physiological functions. The process is mediated through the action of the SNARE (soluble *N*-ethylmaleimide-sensitive-factor attachment protein receptor) complex. For example, exocytosis is mediated by the formation and transition of the *trans*-SNARE complex to the *cis*-SNARE complex during the fusion of vesicles to the cytoplasmic membrane [42]. Another component of this process is the *N*-ethylmaleimide-sensitive factor (NSF). NSF is an adenosine 5'-triphosphatase (ATPase) that promotes the dissociation of the stable *cis*-SNARE complex so as to recycle components during exocytosis [42]. NO is known to inhibit vascular inflammation, possibly through the inhibition of exocytosis of inflammatory granules (Weibel–Palade bodies) in endothelial cells that mediate vascular inflammation and thrombosis [43]. It is now clear that NO inhibits exocytosis of Weibel–Palade bodies through the *S*-nitrosylation of Cys-91 and Cys-264 on NSF [21]. Interestingly, nitrosylation of NSF does not affect its ATPase activity but instead prevents it from disassembling the stable *cis*-SNARE complex during exocytosis [21]. These results suggest that those cysteine residues might be important for NSF to transfer chemical energy from ATP to the mechanical energy required for the disassembly of the SNARE complex [21].

17.5.5 Extracellular Matrix

The extracellular matrix is regulated in part by matrix metalloproteinases (MMPs). MMPs are a family of endopeptidases that degrade the extracellular matrix and have been implicated in a number of diseases [44]. For example, MMP-1 was found to function as a protease agonist of the protease-activated receptor 1 (PAR1), and its signal contributes to the metastatic processes of breast carcinoma [45]. Another MMP, MMP-9, has been found to be elevated in patients after stroke [46]. The important role of MMP-9 in stroke is confirmed by its activation in a mouse stroke model using focal cerebral ischemia and reperfusion. In mice pretreated with MMP inhibitors before cerebral ischemia and reperfusion, the cerebral infarct size was consistently reduced, which supports the importance of MMP-9 activation during ischemia [47]. Interestingly, activation of MMP-9 during ischemia has been recently attributed to *S*-nitrosylation [47]. MMP-9 was found to be activated by *S*-nitrosylation of a cysteine residue in the propeptide domain that coordinates Zn^{2+} in the active site [47]. Activation of MMP-9 seems to have a deleterious effect on neuronal survival. For instance, treatment of neurons with NO-activated MMP-9 increases the rate of apoptosis, and this effect can be reversed by the MMP inhibitor, GM6001 [47]. In the mouse stroke model, activation of MMP-9 activity by focal cerebral

ischemia can be abrogated by the treatment of animals with the specific nNOS inhibitor 3-bromo-7-nitroindazole (3br7NI). Taken together, these results provide insights into how extracellular matrix proteolysis is related to neuronal cell death through *S*-nitrosylation of MMP-9 during ischemia [47].

17.5.6 Cell Survival

NO is well known for its dual effects on cell survival. Both proapoptotic and antiapoptotic pathways have been linked to the action of NO, but how it can mediate such dramatic effects on the cell survival and cell death is still not completely understood. *S*-nitrosylation seems to play an important role in some apoptotic pathways. For instance, both caspase-3 and caspase-9 are *S*-nitrosylated in the mitochondria but only caspase-3 is *S*-nitrosylated in the cytoplasm [48]. Nitrosylation of caspase-3 on the catalytic site cysteine inhibits apoptosis in cells [48, 49]. In Fas-induced apoptosis, one of the actions of Fas is to induce the denitrosylation of caspase-3, supporting the important role of nitrosylation in modulating cell death [49]. In redox-regulated cell survival, NO mediates its effect through the nitrosylation of thioredoxin [22]. Thioredoxin is well known to regulate cell growth, in part by inhibiting apoptosis [50]. In endothelial cells, thioredoxin mediates its function, in part by maintaining the content of *S*-nitrosothiols, and also contributes to the antiapoptotic function [22]. Thioredoxin itself also is nitrosylated at cysteine residue 69, and this modification is necessary for its protective function [22]. Another protein that is well known to be modified by NO through *S*-nitrosylation and to affect cell survival is p21Ras. The Ras GTPase is a small protein that regulates important signaling cascades in cell survival or cell death [51]. The Ras protein functions as a molecular switch that alternates between a GDP-bound “off” state and a GTP-bound “on” state [51]. The on state of Ras interacts with a number of effectors and activates different pathways that control cell growth or cell death [51]. NO activates Ras by *S*-nitrosylation of Cys-118 and enhances the binding of Ras to GTP [52]. For example, in ischemic preconditioning, it has been shown that activation of p21Ras by NO can promote tolerance and cell survival in the face of future ischemic challenge [6].

17.6 PHYSIOLOGICAL FUNCTION OF *S*-NITROSYLATION

In addition to nitrosylation having specific effects on different pathways at the cellular levels, nitrosylation plays a major regulatory role in the cardiovascular system. For instance, nitroglycerin has been used in the treatment of angina pectoris for more than a century because of the vasodilating action of NO. NO induces vasodilatation by activating GC to convert GTP to cGMP, which can subsequently activate G kinase and phosphorylate proteins that induce blood vessel smooth muscle relaxation [53]. It has been proposed that nitrosothiols carried by hemoglobin play an important role in the regulation of blood circulation in response to metabolic demands [54–56]. One model suggests that NO is carried by oxyhemoglobin in its β -globin Cys-93 residue as nitrosothiol [54–56]. In tissues with low O₂ tension, O₂ will release from the hemoglobin and the release of O₂ will promote the transfer of NO from the cysteine to the heme group [54–56]. This transfer will subsequently allow the NO to be released

Figure 17.5 Ventilatory response mediated by NO through S nitrosylation. Oxyhemoglobin from the lung releases O_2 in the brain and tissues with high metabolic demands. In the brain stem, low O_2 tension promotes the release of both O_2 and NO. The released NO can transfer to neurons and react with glutathione (GSH) to form GSNO. GSNO can then be metabolized by γ -GT to form CGSNO. The produced CGSNO can then promote the S nitrosylation of targets in the cell and mediate the ventilatory response to hypoxia [57, 58]. (See color insert.)

from the hemoglobin and enhance vasodilation in tissue with low O_2 tension. Therefore, metabolic demands in active tissues can be met by the vasodilation induced by NO [54–56]. This model provides an attractive mechanism of how NO can regulate blood circulation in tissue with high metabolic rate, but critics have questioned the existence of nitrosylated hemoglobin under physiological conditions and argued that this can only occur in experimental conditions when a bolus of NO is applied [55]. Another controversy of this model is that some studies have suggested that NO is being consumed rather than conserved by oxyhemoglobin [55].

NO released from deoxygenated blood can induce hyperventilatory responses during hypoxia through the action of nitrosothiols in the brain stem [57, 58] (Fig. 17.5). Infusions of nitrosothiols such as GSNO, CGSNO, and S-nitroso-L-cysteine (CSNO) into the nucleus tractus solitarius (NTS) of freely moving conscious rats result in a significant increase of minute ventilation which mimics the physiological response to hypoxia [57]. More importantly, nitrosothiols derived from low-mass fractions of deoxygenated blood could induce similar effects as GSNO, CSNO, and CGSNO, and that UV photolysis release of NO from nitrosothiols derived from deoxygenated blood can completely abolish its effects on minute ventilation. Interestingly, when NTS is treated with a γ -GT inhibitor, acivicin, the effect of GSNO-mediated increases in minute ventilation is completely attenuated, which

indicates that the metabolism of GSNO to CGSNO is essential for this physiological effect of nitrosothiols on respiration [57]. These results strongly support the notion that NO plays an important regulatory function in overall respiration and cardiovascular homeostasis.

Because of the importance of nitrosothiols, one would expect that their levels are tightly controlled. GSNOR appears to have high affinity in metabolizing GSNO. Since GSNO is regarded as a major buffering reservoir of nitrosothiols, one would expect that impairment of its metabolism might contribute to a significant disturbance of physiological homeostasis of NO-controlled pathways. In fact, yeast cells deleted of GSNOR show increased susceptibility to nitrosative challenge [16]. In GSNOR knockout mice, they reproduce and develop normally without any morphological or histological abnormality [59]. GSNOR mice also display normal basal blood pressure, and the basal levels of nitrosothiols in blood are normal. However, they display hypotension when anesthetized with urethane [59]. One of the significant differences of these mice is that when they are challenged with endotoxin like lipopolysaccharide (LPS), they display increased levels of protein *S*-nitrosylation, tissue damage, and mortality rate [59]. The enhancement of endotoxin-induced damage can be partially reversed by treating the GSNOR knockout mice with iNOS inhibitor before the LPS treatment [59]. Taken together, these results support the importance of GSNOR when animals are exposed to increased nitrosative stress.

17.7 NITRIC OXIDE AND NEURODEGENERATION

Neurodegenerative disorders such as Alzheimer's disease (AD) and Parkinson's disease (PD) affect an increasing number of people as the life span of the general population increases. These disorders are usually marked by a progressive loss, associated with aging, of a selective group of neurons. One of the common features of neurodegeneration is the presence of protein aggregates and increased indices of oxidative stress [60–62]. The oxidative stress is particularly viewed as a prime suspect in the pathogenesis of neurodegeneration in relation to aging [60, 61]. For instance, increased lipid peroxidation and nitration of proteins are commonly observed in brain tissue of AD patients [60, 61]. In PD, postmortem pathological studies have revealed that mitochondria complex I dysfunction, reduced glutathione and ferritin levels, and increased lipid peroxidation and iron levels are common [63]. In amyotrophic lateral sclerosis (ALS) patients, consistent increases of 3-nitrotyrosine and nitrated proteins are observed [64]. In all of these disorders, one of the common evaluated oxidative stressors is nitrosative stress. The significant role of nitrosative stress in neurodegeneration can be attributed in part by high NOS activity in the brain and also the intensive energy demand of neurons [65]. The notion that NO is an important player in neurodegeneration is supported by the observation of widespread nitration of pathological inclusions both in neurodegenerative synucleinopathies and tauopathies [66, 67]. It is generally believed that NO mediates its action in the pathogenesis of neurodegeneration mainly through the formation of peroxynitrite, which can damage proteins by reacting with tyrosine residues to form 3-nitrotyrosine, induce peroxidation, and cause DNA damage [68]. However, recent studies have suggested that NO can also contribute to the pathogenesis of PD through *S*-nitrosylation.

17.8 NITROSYLATION AND PD

Parkinson's disease is a common neurodegenerative disorder characterized by movement impairments such as bradykinesia, tremor at rest, rigidity, gait abnormalities, and postural instability [69]. Pathologically, PD is marked by a selective loss of dopaminergic neurons in the substantia nigra par compacta (SNc) and the presence of proteinaceous intracellular inclusions called Lewy bodies [69]. Neuro-biochemically, complex I dysfunction, reduced glutathione, increased lipid peroxidation, and increased levels of iron are also prominent in PD patients due to high level of oxidative stress [69]. The etiology of PD is not known, but it is believed that both environmental and genetic factors contribute significantly to the pathogenesis of PD [69]. This notion is based on the fact that although most PD is sporadic, rare familial cases are also found.

The contribution of environmental factors in PD is confirmed by the discovery of a group of people who developed parkinsonism after the injection of a synthetic heroin in 1980s [70, 71]. Later investigations confirmed the cause of the parkinsonism was due to an impurity, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), in the synthetic heroin [70, 71]. The fact that a chemical can cause the development of PD has elicited an intense interest to find out how MPTP induces dopaminergic degeneration. After injection to the vascular system, MPTP crosses the blood–brain barrier, and once in the brain, it is metabolized by monoamine oxidase B (MAOB) to MPP⁺ [72]. MPP⁺ is then taken up by the dopamine transporter (DAT) into dopaminergic neurons and inhibits complex I in the mitochondria [72]. The inhibition of complex I in the mitochondria results in the production of highly reactive superoxide anions and damages different components in the cell. The superoxide anion also reacts with NO to produce the highly toxic peroxynitrite, which can induce lipid peroxidation and protein and DNA damage and ultimately promotes neuronal cell death.

Apart from environmental factors, genetic components are also believed to contribute significantly to the pathogenesis of PD. In fact, 11 loci have been linked to a rare form of familial PD, and mutations in five genes, including *α-synuclein*, *LRRK2* (leucine-rich repeat kinase 2), *PINK1* (PTEN-induced putative kinase 1), *DJ-1*, and *parkin*, cause hereditary PD [73]. Mutations and triplication of *α-synuclein* and mutations in *LRRK2* cause an autosomal dominant form of PD whereas mutations in *PINK1*, *DJ1*, and *parkin* are linked to an early-onset autosomal recessive form of PD (ARPD). The study of these genes is of intense interest; understanding their function might provide insights into the pathogenic mechanism of PD. This notion is supported by the fact that the linkage of *α-synuclein* to familial PD has led to the discovery that *α-synuclein* is also a major component of Lewy bodies.

Nitrosative stress has also long been suspected to contribute significantly to the pathogenesis of PD [74]. For instance, in the MPTP model of PD in rodents, both nNOS and iNOS knockmice are resistant to MPTP toxicity [72]. In postmortem studies of PD patients, increased nitrotyrosine immunoreactivity and nitrated *α-synuclein* in Lewy bodies are prominent in different brain regions [66, 67, 75]. Although nitrosative stress is viewed as an important factor in the development of PD, the role of nitrosylation is also emerging as an important player in the pathogenesis of PD [74]. *Parkin*, a familial PD-linked gene product, was found to

be *S*-nitrosylated by NO both *in vitro* and *in vivo* [23, 76]. Parkin is a RING finger E3 ligase in the ubiquitin pathway, which targets a number of substrates that are believed to be critical for the survival of dopaminergic neurons [77]. Mutations of *parkin* cause an autosomal recessive form of juvenile parkinsonism, which was first identified in a group of PD patients in Japan [63]. It was later found that mutations in *parkin* could account for up to 40% of the early-onset PD cases [78]. Several studies have shown that parkin can function as a multipurpose neuroprotectant, and this function is dependent on its normal E3 ligase activity [77]. Therefore factors that can interfere with parkin's enzymatic activities might affect the survival of dopaminergic neurons in the face of unfavorable conditions [77]. Parkin consists of a "really interesting new gene" (RING) domain, which is conserved in a group of E3 ligases in the ubiquitin pathway [78]. The RING finger domain is characterized by the presence of a cluster of conserved cysteine residues in the motif, which is critical for the function of the protein. The cysteine-rich domains represent a potential target for *S*-nitrosylation to control the enzymatic activity of parkin. Parkin is modified by NO through *S*-nitrosylation, and *S*-nitrosylation of parkin results in a biphasic modulation of its E3 ligase activity [23, 76]. The *S*-nitrosylation of parkin results into an initial increase followed by a decrease in its E3 ligase activity [23, 76]. The consequence of this biphasic modulation of parkin's E3 ligase activity is not clear, but the chronic inhibition of parkin's activity by the high level of nitrosative stress presents a significant burden for the survival of dopaminergic neurons. This notion is supported by the increase in the levels of *S*-nitrosylated parkin in postmortem brain tissues from PD patients [23, 76]. In the MPTP model of PD, mice treated with MPTP or rotenone there is increased *S*-nitrosylation of parkin. Interestingly, MPTP-induced toxicity in mice results in a biphasic increase of parkin *S*-nitrosylation, which is related to the activity of iNOS and nNOS [23]. ESI-MS and biochemical studies have revealed that the sites of modification are located within the first RING finger and in between RING (IBR) domains, which are known to be important for the function of parkin [23, 76]. The finding that parkin can be *S*-nitrosylated and this modification is substantially increased in PD patients provides a common pathogenic pathway for both the sporadic and the familial forms of PD. In sporadic PD, environmental contaminants can result in increased levels of nitrosative stress and hence lead to the inhibition of parkin E3 ligase activity, which is critical for the survival of dopaminergic neurons. The chronic inhibition of parkin E3 ligase activity by constant elevated levels of nitrosative stress might ultimately promote dopaminergic neuronal cell death and contribute to the development of PD.

17.9 CARBON MONOXIDE AS SIGNALING MOLECULE

Carbon monoxide is well known as a toxic gas produced during incomplete combustion of organic fuel. In animals, CO is generated by heme oxygenase (HO), an enzyme that metabolizes heme to CO and biliverdin [79]. There are two isoforms of HO that have been characterized genetically, HO1 and HO2 [79]. HO1 is inducible under various cell stresses and HO2 is constitutively expressed mainly in brain and testes [2]. Studies have suggested that CO produced from inducible HO1 under cellular stressors might represent a signaling molecule for protective mechanisms in cell survival [2]. HO2, on the other hand, is localized specifically in a selected

population of cells such as olfactory neurons and neurons in the enteric system [80]. The signaling mechanism of CO has been attributed mainly to its action on soluble GC. Regulations of soluble GCs in olfactory and intestinal neurons by CO have been reported, but the exact mechanism is not as clear as the activation of GC by NO [80]. NO and CO may act together to mediate signal transduction in blood vessels [2]. For instance, it was found that both NO and CO can act on GC to dilate blood vessels [80]. In contrast, neuronal culture experiments have suggested that CO can antagonize NO-induced increases in cGMP [80]. Therefore the exact mechanism of how NO and CO can cooperate in signal transduction still awaits further elucidation.

17.10 CONCLUDING REMARKS

Nitric oxide is an important signaling molecule that is involved in the control of a number of cellular and physiological processes. The mechanism of how such a gaseous molecule can achieve this function is beginning to be unveiled through recent studies. *S*-nitrosylation seems to be one of the important redox signaling mechanisms of NO. The continuous study of this pathway will definitely help to improve our understanding of pathogenic mechanisms of different disorders in humans and should provide critical information for the development of new pharmaceutical targets in the near future.

18.1 INTRODUCTION

Depression is one of the most costly brain diseases in the world in terms of pain and suffering, lost work, and mortality from suicide. Depression is not only common but also appears to be increasing in frequency and to be occurring at an earlier age of

onset. Disorders of mood are increasingly understood to be a group of systemic illnesses involving central neurotransmitter imbalances and neuroanatomical disruptions, along with potential dysregulation of immune, autonomic, endocrine, and cardiovascular function. In this chapter emphasis is placed on recent advances in depression research and a discussion is presented of future directions that might catalyze discovery of innovative treatments.

18.1.1 Current Therapeutics Issues

Depression is underdiagnosed and undertreated, even after observed suicidal behavior has been noted [1]. It is associated with lifetime suicidal behavior in 10% of cases, with approximately 3% completing suicide, predominantly men [2]. The one-month U.S. prevalence for depression ranges between 1.5 and 2.5% and the lifetime prevalence is approximately 17% [3]. Employing the disability-adjusted life years (DALYs) methodology, the Global Burden of Disease Study calculated that depression is presently ranked fourth but by 2020 will become the second leading cause of disability, trailing only heart disease (and followed by traffic accidents) [4]. Already in the 15–44-year age group, depression is the leading cause of DALYs worldwide.

18.1.2 Adequacy of Current Antidepressants

Residual symptoms after treatment are more the rule than the exception, and there is concern that further research will conclude that chronicity leads to progressive treatment resistance. This has led to a shift in zeitgeist with new emphasis on treating both acute and residual symptoms more aggressively, with a close eye being kept on functional impairment [5].

About 30% of patients with depression do not meet typical response criteria to an initial course of antidepressants, and furthermore the majority of patients are not symptom free with monotherapy. Additionally, 10–20% of depressed patients do not tolerate an initial trial of antidepressant medication. Thus, 25–35% of patients who complete an adequate trial of an approved antidepressant do not have an adequate response [6]. Moreover a recent clinical meta-analysis indicates that serotonin selective reuptake inhibitors (SSRIs) and the dual monoamine reuptake inhibitor venlafaxine achieve *remission*, as defined, in only 35 and 45% of patients, respectively [7].

These studies highlight the importance of defining novel targets for treatment of people with depression, an area of intensive research effort around the world.

18.2 NEUROCHEMISTRY OF MOOD DISORDERS: MONOAMINES AND THEIR SIGNAL TRANSDUCTION SYSTEMS

There is a broadly acknowledged scarcity of validated drug targets in clinical discovery in psychopharmacology, related in part to the lack of understanding of pathophysiology, poorly differentiated clinical targets (i.e., objective diagnoses), and an absence of objective tests. It is now clear based on various lines of reasoning and empirical data that changing the set point of monoamine transmission does not fully explain antidepressant action but plastic changes in the limbic target areas of

monoamine neuron projections are important in the mechanism of action of antidepressants.

Antidepressants affect multiple presynaptic and postsynaptic processes: for example, changes in cyclic adenosine monophosphate (cAMP) signaling, altered protein kinase or phosphatase activity, changes in neuroplasticity via alteration of neurotrophin expression and neurogenesis, alteration of presynaptic function through effects on synaptic vesicle proteins, changes in activity or receptor binding at specific monoamine receptor subtypes (e.g., α_{1a} receptors), alterations in neuropeptide neurotransmitter binding, upregulation of stress-related receptors such as the glucocorticoid receptors, acting as antagonists or agonists at various steroid receptors, acting as corticotropin-releasing hormone (CRH) receptor antagonists or via alteration of levels of CRH, antagonizing vasopressin receptors, changes in ion channel function including alteration of ion flux and concentrations such as calcium, and alterations in glutamate and γ -aminobutyric acid (GABA) neurotransmission. Further adding to the complexity is new evidence that monoamine neurotransmitters not only are released at terminal fields but also can be released by the *soma and dendrites of neurons themselves* [8]. Thus, antidepressants may effect nonclassical neurotransmitter release. The “conceptual wilderness” in our understanding of antidepressant action since the discovery of the monoamine-based antidepressants [9] will hopefully soon give way to a rich understanding of how interventions in multiple systems and at multiple system levels are therapeutic in subpopulations.

It appears likely that in major depression antidepressants ultimately alter homeostasis or allostasis through complex signaling pathways that affect transcriptional events, the activity of enzymes at the cellular membrane, and patterns of neuronal system activation and connectivity. Key drug targets are critical and possibly unique “biochemical switches” that can be adjusted to alter mood physiology for therapeutic effect, and biologically defined subtypes are needed to further progress in therapeutic development. It appears that the behavioral effects of norepinephrine (NE), serotonin, and dopamine have considerable overlap such that augmenting levels of any one may have antidepressant effects and increasing synaptic levels of more than a single neurotransmitter may be synergistic [7]. Crosstalk between NE neurons, dopamine, and 5-hydroxytryptamine (5-HT) neurons has been documented such that increased NE stimulates 5-HT and dopamine release and 5-HT release at NE neurons reduces NE release. As another example, blockade of the *norepinephrine* reuptake receptor can reduce the uptake of *dopamine* in the frontal cortex since the norepinephrine transporter (NET) has high affinity for dopamine (in fact NET has a higher affinity for dopamine than does the dopamine transporter itself), and dopamine transporters in any event are found at low levels in frontal cortex, suggesting that drugs that inhibit the NET may be antidepressant by affecting prefrontal dopamine signaling [10]. Further study of patterns of reciprocal interaction and crosstalk between these nondiscrete systems may allow us in the future to understand the balance of activity of monoamine systems and tailor therapy [11–14].

18.2.1 Noradrenergic System

The locus ceruleus (LC) is a compact nucleus containing noradrenergic neurons as well as peptide neurotransmitters (e.g., hyopretin and CRH) that influence its activity (for a recent review see [15]). LC neurons can fire in either a tonic or phasic

pattern and electrotonic coupling between neurons can be influenced by neurotransmitters. Release of NE can be accompanied by corelease of the peptide neurotransmitter galanin, which is inhibitory and may alter the firing rate of dopamine neurons, thus altering its hedonic tone. Shifts in the pattern of firing of LC neurons are thought to be of great importance in understanding attentional processes, often disrupted in depression. The LC neurons have long dendritic processes for synaptic contact to influence its activity, and LC neurons may be strongly influenced by anterior cingulate cortex. It has recently been suggested that the A2 group of the medulla may innervate important structures such as the amygdala and nucleus accumbens and thus may be important in affect regulation. Receptors for NE are grouped into α_1 , α_2 , β_1 , and β_2 subtypes.

Chronic therapy with antidepressants results in adaptive receptor alterations in the noradrenergic system. Three genes code for the expression of α_1 subtypes, and these three receptor subtypes (A–C) have distinctive pharmacological properties. Recent data suggest that chronic antidepressants and electroconvulsive stimulation (ECS) may increase frontal cortex expression of messenger ribonucleic acid (mRNA) *specifically* for the α_{1A} adrenoreceptor subtype and as such this receptor may be involved in the action of noradrenergic antidepressants [16]. Repeated administration of antidepressants has been observed to increase behavioral responsivity to α_1 adrenergic agonists (such as aggressiveness and hyperexploration) as well as increasing agonist binding affinity for α_1 adrenoreceptors.

Electrophysiological studies in the hippocampus also support enhanced α_1 responses after chronic antidepressant treatments. Recent data indicate that the novel antidepressant tianeptine, which may increase serotonin reuptake when given chronically, also increases responsiveness of the α_1 -adrenergic system [17].

Single-unit recording from the LC indicates that chronic administration of multiple classes of antidepressants and electroconvulsive stimulation reduce LC baseline and sensory-stimulated firing rates [18]. It has been hypothesized that reducing the firing rate of noradrenergic neurons may be therapeutic, especially in depression with certain clinical features such as psychomotor retardation by reducing the release of inhibitory coreleased galanin neuropeptide onto dopamine neurons in the ventral tegmental area (VTA) [19]. However, reduced firing in the noradrenergic neurons of the LC could simply be a function of increased levels of synaptic or extracellular NE resulting in feedback inhibition of LC firing [18].

The α_2 antagonist yohimbine has been observed to augment the speed of response to fluoxetine [20], and in a very small study ($n = 14$) of bipolar depression the α_2 antagonist idazoxan appeared to have antidepressant effects equal to bupropion [21]. Upregulation of immunolabeled α_{2A} receptors and associated G proteins (G_i) are observed postmortem in suicide victims [22]. This is of interest given the critical importance of these receptors in stress and in regulating levels of monoamines via autoreceptors and heteroreceptors. As well, the efficacy of antidepressants such as mirtazapine and mianserin may in part depend on these receptors. Recent transgenic experiments suggest that the α_2 receptor may act as a “suppressor of depression.” Knockout of the gene for the α_2 receptor increases immobility in the forced-swim test and eliminates the augmentation of forced-swim test activity by imipramine [23]. In contrast, other recent experiments suggest that mice lacking α_{2c} receptors perform on the forced-swim test in the *same* fashion as mice *treated* with antidepressants [24]. Thus, the α_{2a} and the α_{2c} receptors may have complementary and *opposing* roles in

the regulation of mood [25]. If reducing α_{2c} activity is to be used as an antidepressant strategy, it may require some method of targeting only those receptors in the central nervous system (CNS) since an α_{2c} (Del322–325) polymorphism that reduces feedback inhibition of sympathetic NE released in the heart is associated with a markedly increased risk of heart disease [25]. Since some individuals with depression also have memory disturbance, recent evidence that mutation of the α_{2a} receptor impairs working memory could also help us understand the cognitive symptoms observed in depression [26].

Crosstalk between the catecholamine system and steroids may be another novel mechanism through which NE and epinephrine by increasing the sensitivity of glucocorticoid receptors (GRs) to ligand activation could alter mood. A recent study found that amitriptyline prevented the appearance of impairment in spatial memory in aged rats and reduced glucocorticoid levels, and this effect is most likely secondary to NE-mediated alteration in glucocorticoid signaling [27]. Augmentation effects of catecholamines on GR signaling may thus be important in cognitive and emotional processing. The phosphatidylinositol-3 kinase (PI₃-K) signaling pathway activation through β receptors appears to be responsible for this putative enhancement of glucocorticoid activity, and it is tempting to conjecture that antidepressants which are known to downregulate β receptors and influence PI₃-K signaling could act by glucocorticoid receptor sensitization.

Clinical evidence also suggests noradrenergic system involvement in severe depression. Levels of the rate-limiting enzyme for catecholamine synthesis, tyrosine hydroxylase (TH), are upregulated postmortem in suicide victims [28], and chronic treatment with all of classes of antidepressants reduces activity of TH in rodents [29]. In recent years experiments with the catecholamine-depleting agent α -methyl-*p*-tyrosine (AMPT) by Miller and colleagues suggests that some patients with depression, posttreatment, are dependent on specific monoamines to maintain normal mood. Thus, depletion of NE via AMPT challenge in subjects that responded to a predominantly noradrenergic antidepressant but not those responsive to and SSRI results in brief relapse [30]. In addition it appears that treatment refractory depression may be more responsive to agents that augment NE in addition to serotonin as evidenced by robust response rates with venlafaxine and duloxetine and with mirtazapine augmentation studies [7, 31, 32].

18.2.2 Serotonin System: New Understanding of New Drugs

The indoleamine serotonin has a major role in the treatment of various mental disorders and the SSRIs are the most frequently prescribed class of drugs to treat depression in the United States. However, the biochemical mechanism through which serotonergic fibers interact is complex. Neurons, glia, and endothelial cells possess at least 14 distinct receptors, and serotonin is involved “in more behaviors, physiological mechanisms, and disease processes than any other brain neurotransmitter” (reviewed in [33], p. 413). Agents that enhance serotonergic activity such as the SSRIs, which block the serotonin transporter, are effective antidepressants following a substantial latency period. Serotonin in development and adulthood has an important role in CNS neuroplasticity. Clinical and preclinical studies have thus far mostly implicated stimulation and interaction of 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{2A} or

5HT_{2C} receptors in antidepressant action, but this emphasis may in part be an artifact related to the availability of selective ligands for these receptor subtypes.

18.2.2.1 The 5-HT_{1A} Receptor. The 5-HT_{1A} receptor is a seven-transmembrane G-protein-coupled receptor (GPCR) found at both presynaptic locations in the raphe nucleus and postsynaptic locations and is critically involved in regulating mood and anxiety levels. Postsynaptic stimulation in the hippocampus augments synaptogenesis in adult animals via a trophic factor referred to as S-100 β . 5-HT_{1A} receptors also appear to stimulate neurogenesis. 5HT_{1A} receptors signal via a G_{ai}-coupled inhibition of adenylyl cyclase and by hyperpolarization via the opening of a K⁺ channel. 5-HT_{1A} receptor somatodendritic desensitization is considered a key mechanism that allows SSRIs to produce clinical effects in depression by reducing feedback restraint upon serotonin release (reviewed in [34]). However, 5-HT_{1A} autoreceptor downregulation does not appear to be a universal mechanism since tricyclics such as amitriptyline do not cause somatodendritic desensitization [35]. It is also known that a cyclooxygenase-dependent metabolite of arachidonic acid (AA), produced via activation of phospholipase A2 (PLA2), targets the 5-HT_{1A} effector adenylyl cyclase and reduces the responsiveness of the 5-HT_{1A} receptor. This desensitization mechanism is also involved in regulation of the 5-HT_{1B} receptor. 5-HT_{1A} receptor activity is also reduced by activation of protein kinase C (PKC) (via receptor phosphorylation). Neuronal firing rates of serotonin neurons are also affected by feedback loops from the cortex and amygdala. Furthermore, the SSRI fluoxetine reduces hypothalamic sensitivity of 5-HT_{1A} receptors possibly by reducing levels of the G_i family G protein, G_z. Thus, the net effect of antidepressants on 5-HT_{1A} receptors is the result of integration of phospholipid signaling effects on positive and negative regulators, changes in G-protein coupling, and alteration of terminal field feedback [36].

The 5HT_{1A} receptor may counteract the effects of activation of the 5HT_{2A} receptor. Activation of the 5HT_{1A} receptor exerts a hyperpolarizing effect on cortical neurons whereas activation of the 5-HT_{2A} receptor is depolarizing. Activation of 5HT_{2A} receptors results in glutamate release from thalamocortical afferents, and increased levels of glutamate as discussed below may be involved in the etiology of depression. It has been suggested by Marek that either antagonism of 5HT_{2A} receptors or increased activity of cortical 5HT_{1A} receptors would have similar effects of reducing glutamate release (G. Marek, personal communication, 2002). It is tempting to speculate that a drug designed to combine 5-HT_{1A} agonism with postsynaptic 5-HT_{2A} antagonism would have robust antidepressant action.

Recent knockout experiments of the 5-HT_{1A} receptor indicate that the receptor is important early in development with respect to affect-regulated behaviors. 5HT_{1A} null mice have increased anxiety, but “rescue” at a later age in conditional knockouts does not reduce anxiety if the receptor was absent at a developmentally crucial early period [37]. Knockout of the 5HT_{1A} receptor, possibly by eliminating feedback inhibitor, has the effect of reducing immobility in the tail suspension test, simulating antidepressant action. However, rather than being the result of simply increasing synaptic serotonin, challenge studies employing alpha-methyl-para-tyrosine (AMPT) have implicated augmentation of *catecholamine* function in the antidepressant-like behavioral effects of 5-HT_{1A} receptor deletions. However, knockout of the 5HT_{1A} receptor eliminates

the behavioral response to an SSRI, implicating the 5-HT_{1A} receptor directly in their SSRI action [38].

Vilazodone (SB659746-A) is a combined serotonin reuptake inhibitor and 5HT_{1A} partial agonist that provides proof of principle that reduction of somatodendritic 5HT_{1A} receptor activity might provide improved antidepressant effect [39]. Vilazodone augments synaptic serotonin levels compared to conventional antidepressants in rodents and has classic antidepressant effects in the forced swim test (FST). However, there is an inverted-U-shaped curve such that at high doses it loses its antidepressant-like behavioral effects. This nonlinear behavior of the drug may indicate that at low doses, due to vilazodone's partial 5HT_{1A} agonist effect, it relatively reduces somatodendritic activity or facilitates desensitization of these receptors while at higher doses it begins to antagonize activity at postsynaptic limbic 5HT_{1A} receptors, which diminishes its antidepressant effect.

Paradoxical [rapid eye movement (REM)] sleep is increased in stress and in depression, and depressed subjects may have a decreased number of postsynaptic 5-HT_{1A} receptors. Like depressed humans, 5-HT_{1A} knockout mice have abnormally increased density of REM sleep and do not have normal REM sleep rebound after stress or sleep deprivation [40]. Since 5-HT_{1A} receptors and 5-HT_{2A} receptors have antagonistic effects on intracellular signaling, increased sleep continuity with 5-HT_{2A} antagonists might be related to a relative increase in 5-HT_{1A} signaling.

18.2.2.2 DARPP-32 and Mechanism of Action of SSRIs. Attempts at understanding the temporal delay in onset of antidepressant effects have recently focused on signal transduction cascades and changes in gene expression. Evidence has suggested that antidepressants, including the SSRIs, augment activity in the cAMP-dependent protein kinase A (PKA) pathway in the cortex and hippocampus [41]. DARPP-32 (dopamine- and cAMP-regulated phosphoprotein of molecular weight 32,000) is a protein concentrated in the prefrontal cortex and striatum. Chronic treatment of mice with fluoxetine increases levels of DARPP-32 in the prefrontal cortex and hippocampus. DARPP-32 regulates the efficacy of various ion channels and ionic receptors via phosphorylation. Serotonin acts on DARPP-32 synergistically through 5-HT₂, 5-HT₄, and 5-HT₆ receptors to convert DARPP-32 into a potent inhibitor of protein phosphatase-1 (PP-1), which results in reduced protein dephosphorylation. As a result, transcription factors that may be relevant in the treatment of depression and in neurodegenerative disorders such as cAMP response element binding protein (CREB) would have increased activity. Other antidepressants and lithium also increase levels of rat frontal cortex DARPP-32. Since antidepressants may act through the brain-derived neurotrophic factor (BDNF), it is interesting to note that BDNF KO mice have significantly reduced levels of DARPP-32. A receptor regulated by DARPP-32 is the α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor, a glutamate receptor subtype implicated in depression and cognition, as discussed below. Chronic treatment with fluoxetine increases phosphorylation of the GluR1 AMPA receptor subunit and the DARPP-32/PP1 signaling cascade is involved in this process. In DARPP-32 KO mice fluoxetine is significantly less efficient in augmenting phosphorylation of AMPA GluR1 subunits. As well, DARPP-32 KO mice have a markedly reduced response to fluoxetine in the tail suspension test for antidepressant efficacy. Therefore a novel mechanism of action for SSRIs may be via alteration of "kinome"-regulated processes (i.e., changes in

kinase/phosphatase balance) that increase AMPA receptor currents and result in AMPA receptor-regulated changes in synaptic plasticity [42, 43].

18.2.3 Monoamine Transporters

Serotonin transporters (SERTs) and NETs are both high-affinity targets of antidepressant agents and both transporters are the product of a single gene residing in the same gene family. Blakely has noted that a single gene coding for transporters indicates that polymorphisms that affect the function of the receptor and thus the clinical phenotype will be expressed in both the CNS and periphery transporters [44]. Transporter expression and sequestration are regulated by kinase activity such as PKC, and SSRIs alter the gene expression of the kinase involved in the regulation of SERT expression.

As mentioned, NET inhibitors (e.g., desmethylimipramine, which is a highly selective NET inhibitor) have been used as antidepressants for many years. Recently, the additional two highly selective NE reuptake inhibitors reboxetine and atomoxetine were marketed. Recent transgenic experiments support potential importance for NET in depression. Xu and colleagues observed that NET knockout mice behaved as if treated with antidepressants in that they had locomotor hyperresponsiveness to stimulants [45]. However, reduced levels of NET have been observed in the LC postmortem in depression, possibly reflecting an adaptive response to decreased levels of extracellular NE [46].

NET polymorphisms have been identified in association with abnormal cardiovascular function. A proof-of-concept study identified polymorphism is based on observation of patients with orthostatic intolerance [47] along with fatigue, headaches, syncope, and attention-deficit symptoms [44]. Peripheral manifestations of NE or serotonin system abnormalities could be important markers for identifying and subtyping mood and anxiety disorders or enriching clinical samples for genetic studies or pharmacological trials.

18.2.4 Regulators of G-Protein Signaling as Potential Drug Targets in Mood Disorder

The dramatic efficacy of antidepressants effecting biogenic amines is related to their powerful influence on the family of GPCRs. The biogenic amine antidepressants alter receptor thermodynamics toward a distinct drug-bound ensemble. GPCR activation alters the specific intracellular ensemble of G proteins and may result in receptor internalization or phosphorylation and increases interaction with auxiliary membrane affiliated proteins. Antidepressants thereby alter the activity of enzymes in multiple signal transduction pathways that modify neurophysiological response [48].

GPCR signal transduction has been considered as a three-component model with the seven-transmembrane surface receptor coupled to a membrane-associated heterotrimeric G-protein complex. Recent data indicate that GPCRs form homo- and hetero-oligomeric complexes, and this revelation may prove important for future drug design and for understanding complex neurotransmitter system interactions and synergisms. Binding of guanosine triphosphate (GTP) to a G α switch region engages a specific effector for each G α subtype [49].

A newly discovered component of the GPCR signaling cascade is a family of proteins known as regulators of G-protein signaling (RGS proteins). RGS proteins are mainly GTPase-accelerating proteins (GAPs) for $G\alpha$ (i.e., they augment G-protein inactivation), and thus potential small-molecule *inhibitors* of tissue-specific RGS proteins should lead to enhanced signaling from agonist-bound GPCRs. Wyeth-Ayerst Research has described transgenic rodents that are insensitive to RGSs at specific $G\alpha$ subtypes in the CNS. They exhibit heightened serotonin receptor signaling at 5-HT₂ receptors and muscarinic receptors. The prolonged signaling observed via $G_q\alpha$ -PLC β is similar to that seen after lithium administration in normal rodents. Electroconvulsive seizures are known to increase CNS expression of RGS2 in the amygdala, cortex, striatum, and hippocampus, while RGS10 is decreased in dentate gyrus and parietal cortex. Unpredictable stress or corticosterone increases LC and hypothalamic expression of RGS4. RGS7 is increased in brain of mice treated with the proinflammatory cytokine tumor necrosis factor- α (TNF- α).

Tissue-specific enhancement of GPCR signaling by RGS small-molecule inhibitors is thus a novel antidepressant strategy and could greatly increase signal throughput via D2/D4 receptors in the basal ganglia and a RGS9 inhibitor plus a D2 agonist may be effective at lower doses and with fewer side effects in Parkinson's disease and depression. Thus, novel therapeutics through either stimulation or inhibition of RGS proteins in specific brain regions may enhance catecholamine or serotonin signaling or have mood-stabilizing effects similar to lithium.

18.2.5 Neuroplasticity and Use-Dependent Activity

Preliminary insight into the mechanism underlying an organism's ability to adapt to and learn from its environment began with the observation that neurotransmitter stimulation of neurons alters gene transcription. Use-dependent plasticity is seen in neuronal networks and synapses, and the downstream expression of transcription factors that sculpt neural circuits is critical to our understanding of mood states and antidepressant action. The term "neuroplasticity" subsumes *functional changes* in the nervous system and can be discussed at different levels. Plasticity can be at the level of synaptic anatomy and connectivity—changes in synaptic plasticity via alterations of dendritic function, synaptic remodeling, synaptogenesis, or neurogenesis. Plasticity can also refer to changes in long-term potentiation or be discussed in terms of behavioral plasticity [50]. Neurotransmitters, neuromodulators, and hormones that influence intracellular signaling cascades mediate these functional changes. Recent morphometric studies and pharmacological studies suggest the possible importance of neuroplastic events in the etiology and treatment for affective disorders [51–54].

18.2.6 Neurotrophic Hypothesis in Depression

The neurotrophins are a family of related, secreted peptides that powerfully affect development and the adult functioning or plasticity of the CNS [55] (see also chapter 8 in volume III of this handbook). Neurotrophins regulate neuronal survival and control neurite growth in either a positive or negative direction via interactions or functional interplay between two types of transmembrane glycoprotein receptors. Thus neurotrophins are critical for *selection of functional neuronal connections in the CNS*, which makes them prime candidates for understanding the complex neurodevelopmental and

environmental factors in depression. Neurotrophins signal via the *trk* family of receptor tyrosine kinases, which have specificity for neurotrophin ligands, and via the pan-neurotrophin receptor, p75 (p75^{NTR}), which is a common receptor for the whole neurotrophin family of ligands. BDNF infusion after neurotoxin exposure markedly enhances plasticity and neurite outgrowth in the serotonin system of the adult rodent brain [56] (see also Chapter 20). Intermediate doses of BDNF were most effective, suggesting an inverted-U-shaped dose–response curve.

In recent years Duman and the Yale group have proposed a new dramatic molecular and cellular theory of depression [57, 58] (see also Chapter 20) based on increased knowledge of the intracellular cascades that are stimulated by antidepressants that result in the generation of BDNF, which along with NT 4/5 activates TrkB receptors. TrkB receptors are located both in GABAergic interneurons and glutamatergic pyramidal neurons and granule cells. TrkB receptors are also found in the raphe neurons of the rat raphe nucleus [59]. BDNF has both presynaptic effects that facilitate neurotransmitter release and postsynaptic effects [60, 61] on plasticity. BDNF affects the balance of potentiation and inhibition in circuits by augmentation of the level of AMPA receptor–mediated miniature excitatory postsynaptic currents (mEPSCs) and by increasing the frequency of miniature inhibitory postsynaptic currents (mIPSCs) [62].

The capacity of neurotrophic factors to provide trophic support and influence neuroplasticity may be through activation of the mitogen-activated protein kinase (MAPK) pathway, which includes the extracellular signal-regulated kinase (ERK), and via the PI₃-K/Akt signaling pathway. If neurotrophic factors are involved in depression, it could indicate a primary deficiency of neurotrophic factors or that increased levels of such factors are necessary to overcome reduced functioning of the MAPK/ERK signaling pathways critical for transactivation of specific genes. Protection against excitotoxicity and neuroendangerment and increased levels of BDNF may result from induction of c-Fos that heterodimerizes with c-Jun to form the AP-1 transcription factor. Thus, mice in which c-Fos has been knocked out have increased excitotoxicity and neuronal cell death and altered levels of BDNF [63].

A critical transcription family for neurotrophin expression is CREB, which is made up of CREB, CREM (CRE-modulatory protein), and ATF1 (activator transcription factor 1). CREB turns on the BDNF gene (and BDNF release in turn stimulates CREB) and the NMDA receptor–linked molecule nNOS (neuronal nitric oxide synthetase) as examples. Following synaptic activity calcium entry through specific routes stimulates MAPK-dependent phosphorylation of CREB. Calcium can also eventually result in dephosphorylation of CREB via activation of protein phosphatases PP1 and PP2A. The neurotrophic hypothesis of antidepressant action suggests that many antidepressants increase expression of CREB and phosphorylated CREB, which upregulates among its gene targets BDNF [64]. Antidepressants may therefore act by increasing synaptic plasticity in mood disorders [65].

Stress markedly reduces hippocampal neurotrophin levels in model systems [66], and the hippocampal atrophic changes caused by stress are reversible by central BDNF administration in animal models of depression [67]. Stress-related changes in BDNF levels in the hippocampus may result from alteration in the balance of excitatory and inhibitory input as well as circadian and stress-related changes in glucocorticoid levels [68, 69]. Moreover, corticosterone shifts the intracellular location of BDNF away from the nucleus of neurons with concomitant increased cytoplasmic

levels, although the significance of this is unclear [70]. Depressive symptoms including motor slowing and agitation are associated with a decrease in BDNF expression in an ethanol withdrawal model, and fluoxetine both reverses the anxiety phenotype and prevents the decrease in BDNF immunolabeling [71]. However, stress does not universally decrease BDNF expression. In fact, immobilization stress has the *opposite* effect—and thus enhances BDNF mRNA levels and protein in the rat hypothalamus [72], suggesting that BDNF may also be important in the plasticity processes that integrate stress responsivity in the hypothalamic–pituitary–adrenal (HPA) axis.

Antidepressants, but not other psychotropics such as cocaine, increase BDNF and are neuroprotective in animal models [73, 74]. Furthermore, BDNF directly administered into the hippocampus has sustained antidepressant effects in a rodent model of depression as early as three days after a single infusion and the effect size is comparable to that observed after antidepressant administration [75]. Moreover, mice with knocked-down levels of BDNF have abnormal levels of aggression and reduced levels of brain serotonin [76]. Normal levels of BDNF and TrkB signaling are necessary for behavioral response to antidepressants on the forced-swim test. Furthermore, antidepressants are observed to specifically increase TrkB autophosphorylation in the prefrontal cortex, cingulate cortex, and hippocampus, suggesting increased neurotrophic signaling as the mode of action of antidepressant [77].

Further evidence of the critical importance of BDNF for neuroplastic responses to pharmacological stimulation comes from the field of addiction research, where the neuroadaptive effects of opiates on the LC and noradrenergic system are markedly reduced in mice with a conditional knockout of BDNF in the postnatal period [78]. As noted, sleep deprivation can result in a limited antidepressant effect and can induce mania in bipolar patients. In rats it appears that BDNF and TrkB as well as CREB may be upregulated during waking hours and during sleep deprivation [75, 79].

18.2.7 BDNF Clinical Findings

Reductions in BDNF are suspected in neurodegenerative disorders such as Alzheimer's disease [80] and may be reduced in some individuals with depression. In a postmortem study, prefrontal cortex levels of the transcription factor CREB are reduced in major depression and restored in those treated with antidepressants [81], and hippocampal BDNF immunoreactivity is increased in depressed subjects treated with antidepressants. BDNF is increased in the hippocampus in depressed patients who were being treated with antidepressants at the time of death compared to those subjects untreated [82].

BDNF may be transported in a bidirectional fashion across the blood–brain barrier [83]. Positive correlation has been reported between serum and cortical BDNF levels [84]. Karege and colleagues observed in mostly depressed subjects ($n = 30$) that BDNF serum levels were reduced compared to controls, with the greatest decrease in female subjects. There was considerable overlap with controls, but the reduced levels correlated with depression severity in patients [84]. Reductions in serum levels have also been reported in other psychiatric populations, including schizophrenia [84]. It is possible that in a subpopulation, of depressed patients peripheral levels of BDNF or other neurotrophic substances that can be transported to and from the CNS such as insulin-like growth factor-1 (IGF-1) may be candidate biomarkers of disease [85]. Although it is clear that platelets contain significant quantities of BDNF that is

released at sites of injury containing TrkB, the relevance of peripheral BDNF measurements for understanding brain function is unknown [86].

The BDNF gene is located on the short arm of chromosome 11 (11p13–14). There are two studies with suggestive scores of logarithm of the odds of linkage (LOD) to this region of 1.89–1.95 in bipolar pedigrees [87, 88]. BDNF has been suggested as a candidate gene or risk locus for genetic association study [89] and a recent family-based genetic association study has evidence for linkage disequilibrium between specific BDNF polymorphisms and bipolar disorder using the family-based association test. Thus a gene variant in the vicinity of the BDNF gene may confer risk of bipolar disorder [90], though the gene variant's functional significance is unknown. In addition a transmission disequilibrium test found that a specific BDNF haplotype had decreased transmission to bipolar probands, which could suggest that this haplotype is a protective factor against disease [90].

18.2.8 Potential Pharmacophores to Modulate Neurotrophin Expression

Even if the neurotrophic hypothesis of depression is proven to be substantially correct, there is currently an absence of small-molecule agonists for Trk receptors. An alternative strategy is to discover drugs that upregulate Trk receptors or increase their sensitivity. Furthermore, BDNF saturable blood–brain barrier penetration and the existence of truncated TrkB receptors for BDNF that can sponge up growth factors limit our current capacity to augment trophic activity [91]. Moreover, it is now well established that neurotrophins, in addition to involvement in maintaining neurons, have a critical role in moment-to-moment modulation of activity-dependent neuronal plasticity. Hence, indiscriminate or wholesale application of neurotrophins is likely to result in dramatic levels of serious side effects and neuronal circuit dysfunction. It is possible that strategies able to locally supply neurotrophins to projection nuclei such the LC or dorsal raphe may prove successful. Trials thus far using neurotrophin administration for amyotrophic lateral sclerosis and other neurodegenerative disorders have not been unsuccessful [92].

Small-molecule drugs have been found that possess neurotrophic activity. The immunosuppressant FK506 that binds to the immunophilin 12-kDa FK506 binding protein FKBP 12 has neurotrophic properties. Immunophilins were initially identified as receptors for immunosuppressant agents, including cyclosporin A and FK506. Immunophilins are highly concentrated in the brain compared with peripheral tissues. Derivatives of the immunosuppressant drugs have been developed that are neurotrophic without suppressing immunity. Small molecules have been developed such as GPI-1046 with *in vivo* and *in vitro* neurotrophic properties, and these drugs promote, for example, the regrowth of dopamine and serotonin neurons in lesion experiments and may be neuroprotective. These drugs are currently lead compounds for the treatment of neurodegenerative disorders and may be worthwhile testing in severe mood disorder as evidence builds supporting a neurotrophic factor deficiency hypothesis in depression.

Other approaches might be to indirectly stimulate BDNF production by, for example, the use of small molecules that modulate AMPA receptor function known as AMPAkinases (*vide infra*) and BDNF reciprocally modulates the expression of AMPA receptor proteins on neurons [93]. Another mechanism that may be exploited in the future to finely tune the level of neurotrophic activity and neuroplasticity is

changing levels of cyclic guanosine monophosphate (cGMP) or nitric oxide (NO). Recent data indicate that within the hippocampus the NO/cGMP/protein kinase G (PKG) signaling pathway may be critically involved in the rapid downregulation of BDNF [94]. The success influencing this pathway in a tissue-specific fashion in the treatment of erectile dysfunction using sildenafil [95] suggests that CNS-specific drugs may be of interest in treating depression or neurodegenerative disorders. BDNF and neurotrophin (NT) 4/5 via an autoregulatory pathway stimulate further production of neurotrophic factors. These neurotrophic factors may in turn increase their own levels by increasing levels of AMPA ionic glutamate receptor subunit GluR1 [96].

However, there is some evidence that the acute or subacute effects of antidepressants in behavioral immobility antidepressant assays (i.e., the forced-swim test or tail suspension test) are not mediated via CREB-dependent transcriptional products [97]. This was concluded based on experiments with CREB-deficient mice where the behavioral (i.e., decreased immobility in the FST) and endocrine effects of subchronic antidepressants were similar in wild-type and CREB-deficient mice [97]. An additional criticism of the neurotrophic hypothesis is that conditional knockouts for BDNF have an anxious phenotype but do not show obvious signs of depression [98]. As well, in contrast to the hippocampus, it appears that increased levels of CREB and BDNF in the dopamine-rich nucleus accumbens may *reduce* hedonic tone and have a depressogenic effect. It appears that regional overexpression of CREB specifically in the shell of the nucleus accumbens “gates” strong affective experiences with either a positive or negative valence. This is probably mediated by downstream influences on the regulation of peptide or nonpeptide neurotransmitters or neuromodulators controlled by CREB sites [99]; thus CREB in the nucleus accumbens shell may be setting the “gain” for affective or hedonic experience. Moreover, CREB overexpression in this specific tissue compartment *increases* immobility during swim stress. Changing levels of CREB in particular functional circuits may lead to vastly different phenotypes [100], and regional analyses of CREB levels are necessary to understand its function in depression. This highlights the importance of regional specificity in understanding the function of key neuroplastic modulators in depression [101].

18.2.9 Excitatory Amino Acid Receptors and Transporters in Neurons and Glia

Most neurons as well as glia have cell surface excitatory amino acid (EAA) receptors. Glutamate and other EAAs operate via four distinct classes of receptors. These include three heterogenous classes of ionotropic EAA receptors (iGluRs) [N-methyl-D-aspartate (NMDA), AMPA, and kainate receptors (KAs)] and a heterogenous class of G-protein-coupled EAA receptors (mGluRs). All of these receptors are thought to have an important role in CNS signaling in neurons and glia and as such are important therapeutic targets in neuropsychiatric diseases [102].

Cloning of the iGluRs and the mGluRs has been the basis for a dramatic expansion of research in the EAA receptor arena. At present, six NMDA receptor subunits (NR1, NR2A–2D, and NR3A) have been cloned, four AMPA receptor subunits (iGluR1–4) have been characterized, and five subunits for the KA receptors (iGluR5–7, KA1, and KA2) have been discovered [103].

The dynamic balance of glutamate is very sensitive to alterations in energy supply, and a highly efficient transport system protects neurons against the neurotoxic effects

of glutamate (reviewed in [104]). Glutamate transporters are energy dependent and essentially are the only mechanism to remove glutamate from the synapse. Thus, the brain is thermodynamically metastable due to the large amounts of toxic intracellular glutamate held in check via energy-demanding processes. Inhibition of glutamate uptake by neurons and astrocytes results in rapid buildup of glutamate, for instance, in ischemia. A *deleterious network hypothesis* has been proposed in which activation of glutamate receptors can lead to increasing levels of excitatory neurotransmitter signaling, higher energy demands, and increased production of toxic free radicals [104].

Synaptic spine dimensions are also regulated by glutamate receptor activity. The structural organization of various synapses and their relationship to astrocytes and glutamate transporters (GLT1 and GLAST) control levels of glutamate and thus activity. It has been shown in the supraoptic nucleus of the hypothalamus that there is a plastic restructuring of the neuropil leading to withdrawal of astrocytic processes at glutamatergic synapses which alters glutamate levels and glutamate release via activation of metabotropic glutamate receptors [105]. The relationship between glia and the synapse is mediated, at least for Bergmann glia that ensheath Purkinje cells, by AMPA receptor-mediated processes [106]. Crosstalk between synapses through spillover of glutamate may also have a role in understanding changes in excitability and neurotoxic effects. For instance, glial glutamate transporters in some instances may be poorly oriented in the hippocampus to deter crosstalk between nearby synapses due to limited three-dimensional astrocytic process coverage between them [107]. This could help explain particular vulnerability of the hippocampus to excitotoxicity in stress-related processes such as depression [108]. S100 β is a calcium binding protein primarily expressed by astrocytes and after secretion has a neurotrophic role.

Trophic substances released by astrocytes may be important for the maintenance of neuronal health. S100 β has been proposed as a neurotrophic factor that may protect neurons against glutamatergic toxicity [109], although high levels of glutamate can also reduce S100 β production, further reducing neuronal resilience [110], and too great an increase in S100 β can also be deleterious. S100 β is released in response to stimulation of 5-HT_{1A} receptors such that serotonergic antidepressants could have therapeutic action via this novel mechanism of increasing levels of S100 β . Recent imaging data suggest that antidepressants may protect against a reduction in hippocampal volume observed in depression. Recent advances using ¹³C nuclear magnetic resonance spectroscopy following acetate infusion indicate that glutamate/glutamine cycling between astroglia and neurons is the central pathway to replenish neuronal glutamate stores, and this imaging technique may be used in the future to study the role of glutamate signaling in depression [103].

18.2.10 Clinical Evidence for NMDA Receptors in Mood Disorders

Evidence for abnormal glutamatergic neurotransmission involvement in mood disorders can be traced back to the 1950s when the antitubercular drug D-cycloserine, a partial agonist at the NMDA glycine allosteric modulatory site, was observed to have mood-elevating effects. Moreover, amantadine is a low-affinity uncompetitive antagonist of NMDA receptors, and case reports and studies indicate that this antiviral agent has antidepressant activity in unipolar and bipolar depressed patients and in depressed subjects with Parkinson's disease [111].

The antiepileptic drug lamotrigine is widely prescribed for its antidepressant and mood-stabilizing effects in the treatment of bipolar depression, and it has been suggested that reducing pathological glutamatergic activity may be the mechanism of action [112–116]. These same agents are effective in several neurological conditions that may involve excessive activation of glutamate receptors in addition to convulsive disorders (e.g., opiate dependence, neuropathic pain, ischemia, and traumatic brain injury). Potent noncompetitive NMDA antagonists such as MK801 or ketamine may with prolonged exposure cause cortical neurotoxicity and acutely result in psychosis. A proposed mechanism is via putative NMDA receptor hypofunction that results indirectly (via GABA interneurons) in disinhibition of critical ascending glutamatergic (thalamocortical) and cholinergic (basal forebrain-cortical) pathways that may result in excessive activity at AMPA and kainate receptors [117, 118].

The channel-blocking NMDA antagonist ketamine has been observed to have rapid (within 72 h) antidepressant effects distinct from its euphorogenic effects [119], and lamotrigine has been observed to prevent the psychotic-like effects of the NMDA antagonist ketamine in normal humans [120]. Farber and colleagues have proposed that anticonvulsants may be effective by dampening voltage-gated sodium channel activity required for action potential initiation and thereby limiting activity in disinhibited ascending pathways. However, such reasoning is unlikely to fully explain the differences in psychotropic and neuroprotective effects between anticonvulsant agents [121]. For example, recent evidence suggests that the antidepressant lamotrigine selectively reduces action potential generation in dendrites without having a similar effect at the soma and that this is related to an increase in the “hyperpolarization-activated cation current (I_h), a voltage-gated current predominantly found in dendrites” [122, p. 21]. Lamotrigine may also have a portion of its therapeutic effects in epilepsy and depression via potentiation of a hyperpolarizing K⁺ current [123].

18.3 CONCLUSIONS

Despite the large number of potential novel drug targets, there is concern that there is a slowdown in the development of truly innovative drugs for many conditions. In the area of affective disorders, some of this difficulty reflects the high rate of negative and failed trials, related in part to the tremendous genetic and phenotypic heterogeneity in depression, and the lack of biological markers to guide drug development. Existing or novel endophenotypes that reduce disorders to discrete component units and ultimately fundamental units linked to pathophysiology may help move translational research forward. Clinical and genomic approaches are needed to clinically subgroup patients more precisely. Refinement of measurement tools including imaging techniques may lead to the definition of new endpoints, and biomarkers may be developed based on dissected components of current consensus syndromes that measure disease state with accuracy and objectivity. There is great promise and investment in the idea of high-throughput screening of targets determined either by evaluating disease-linked susceptibility genes and proteins (i.e., the candidate target approach) or via the open-target approach using differential display (e.g., DNA expression chips) and proteomics with postmortem samples from patients (or from animals treated with psychotropic agents). DNA databases and bioinformatics

approaches may also be used to uncover motifs or domains that have features suggestive of disease relevance [124]. Characterizing drug target effects on neurotransmitters, transcription factor levels, or brain circuitry implicated in depression can then validate novel drug targets identified. Also, if drugs with known psychotropic effects interact or regulate expression of a candidate gene or protein, this would provide further confirmation of the target's relevance.

19.1 INTRODUCTION

The first theories of depression were based on the discovery that drugs with antidepressant efficacy could influence synaptic levels of monoamines, most notably serotonin (5-HT) and norepinephrine (NE). This included the monoamine oxidase inhibitors that block the metabolism of 5-HT and NE and the tricyclic antidepressants that block the reuptake of monoamines. These findings resulted in the monoamine hypothesis, which stated that antidepressant activity was due to an increase in levels of 5-HT and NE and that depression was due to abnormally low levels of these neurotransmitters. The 5-HT and NE systems have been and continue to be the focus of intense basic and clinical investigations into the neurobiology of depression. However, the time lag in the therapeutic response and the lack of effect of acute monoamine depletion on mood suggest that there are additional factors involved in the etiology and treatment of depression [1].

The requirement for long-term treatment to produce a therapeutic response has resulted in the widely held hypothesis that adaptations or neural plasticity play a major role in the actions of antidepressants [2–4]. This hypothesis posits that the increase in levels of 5-HT and NE leads to regulation of receptor-coupled intracellular signaling pathways and regulation of gene expression that ultimately control neuronal function that underlies behavioral alterations. There are a number of adaptations that have been identified, but one that has gained increasing interest is the regulation of neurotrophic factor expression and related signaling [1, 5]. This hypothesis is based on a combination of timely basic and clinical research studies of stress, depression, and antidepressant responses in animal models and humans over the past 10 years. This is meant to be not a complete review of the literature but rather an overview of studies relevant to a neurotrophic hypothesis of depression/antidepressant response.

19.2 NEUROTROPHIC FACTORS AND INTRACELLULAR SIGNALING CASCADES

One of the most highly studied growth factor systems in the central nervous system is the nerve growth factor (NGF) family, and the major focus of this chapter is on one of the members of this family, brain-derived neurotrophic factor (BDNF). However, there are many other important neurotrophic/growth factor systems that are now being examined in the context of complex normal and abnormal neuronal and behavior functions (Table 19.1). A brief review of the major neurotrophic/growth factor systems is provided in this section, particularly where there is information that relates these factors to stress, depression, and antidepressant responses (see also Chapter 8 in Volume III of this handbook). One of the key features that link these different growth factor systems is the activation of intracellular tyrosine kinase signaling pathways (Table 19.1). This could account in part for the overlap and function of these diverse growth factor systems in the actions of stress and antidepressant treatment.

19.2.1 Nerve Growth Factor Family

This neurotrophic factor family is comprised of NGF, BDNF, neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4/5) (Table 19.1). These factors were originally identified for their role in the development of the central nervous system, including neurogenesis, differentiation, and survival. However, members of the neurotrophic factor family are also expressed in the adult brain, the expression of certain factors (e.g., BDNF) is dependent on neuronal activity, and these factors can modulate the survival and function of adult neurons [6]. The receptors, referred to as Trk (derived from troponin/receptor kinases), have an extracellular binding domain and an intracellular tyrosine kinase domain. There are three different receptors, TrkA, TrkB, and TrkC, that bind NGF, BDNF, and NT-3 and NT4/5, respectively, although NT-3 can also bind TrkB.

Binding of a neurotrophic factor ligand to a Trk receptor leads to activation and autophosphorylation of the intracellular tyrosine kinase domain, resulting in association with proteins containing a Src homology (SH) domain. This can lead

TABLE 19.1 Neurotrophic and Growth Factor Families, Receptors, and Kinases

Family	Members	Receptor/Kinase
Nerve growth factor (NGF)	NGF, BDNF, NT-3, NT-4/5	TrkA-C, tyrosine kinases
Vascular endothelial growth factor (VEGF)	VEGF-A,B,C,D,E, PlGF, PDGF-A,B	R1 (Flt-1), R2 (Flk-1), R3 (Flt-4), tyrosine kinases
Fibroblast growth factor (FGF)	FGF2, many others (FGF1–23)	FGFR1–4, tyrosine kinases
Insulin-like growth factor (IGF-1)	Insulin, IGF-1, IGF-2	IGF-1R, tyrosine kinase
Transforming growth factor- β (TGF- β)	TGF- β 1–5, activins/inhibins	T- β RI, RII, Ser/Thr kinases, activinRI, RII, Ser/Thr kinases

Figure 19.1 BDNF, VEGF, FGF-2, and IGF-1 can activate the same signal transduction cascades. These factors bind to receptors that have an extracellular binding domain, a transmembrane domain, and an intracellular tyrosine kinase domain. Binding of each factor to its receptor results in autophosphorylation of tyrosine residues (Y). This in turn can lead to activation of one or more signaling cascades as indicated by multiple arrows, including the PI-3K, ERK, and PLC- γ pathways. (See color insert.)

to activation of different signal transduction systems depending on the cell type (Fig. 19.1). These include the Shc/Ras extracellular regulated kinase (ERK) pathway [also referred to as the microtubule-associated protein kinase (MAPK) cascade], phospholipase C- γ (PLC- γ) and protein kinase C (PKC), phosphatidylinositol-3'-OH kinase (PI-3 K), and protein kinase B (AKT).

19.2.2 Other Classes of Neurotrophic/Growth Factors

19.2.2.1 Vascular Endothelial Growth Factor (VEGF). VEGF exerts powerful effects on vascular permeability but also induces angiogenesis and endothelial cell proliferation [7]. VEGF is a heparin binding glycoprotein that is secreted as a 45-kDa homodimer. There are five different members of the VEGF family, VEGFA–E (Table 19.1). Related growth factors include placental growth factor (PlGF) and platelet-derived growth factors (PDGF) A and B. These ligands bind to one of several different receptors, VEGFR1 (also known as Flt-1), VEGFR2 (also known as Flk-1 or KDR), and VEGFR3 (also known as Flt-4). The neuropilin receptors 1 and 2 are also related to the VEGF receptors. The VEGF receptors have an intracellular tyrosine kinase domain and multiple immunoglobulin G (IgG)-like extracellular

domains. The VEGF receptors couple to multiple intracellular cascades via interactions with many of the same signaling proteins activated by the neurotrophin-Trk receptors, including Shc/Ras-ERK, PLC-g-PKC, and PI-3K-AKT (Fig. 19.1).

19.2.2.2 Fibroblast Growth Factor (FGF). The FGF family consists of 23 different members, 10 of which are expressed in the brain [8] (Table 19.1). These factors play a role in neuronal development, including neurogenesis, differentiation, axonal branching, and neuronal survival. In addition, the FGF family members are involved in the adult neuronal function, most prominently neuronal repair, as well as in learning and memory. There are four FGF receptors, R1–4, which have three extracellular Ig-like domains and an intracellular tyrosine kinase domain. FGF binding leads to activation and autophosphorylation of the receptor. This leads to interactions with SH2 domains of signaling cascades and activation of intracellular signaling proteins, including src and PLC- γ -PKC as well as Shc/Ras-ERK and Crk (Fig. 19.1).

19.2.2.3 Insulin and Insulin-Like Growth Factor (IGF-1). This family of growth factors is comprised of insulin, IGF-1, and IGF-2 (Table 19.1). These factors are important mediators of growth as well as metabolism in both the peripheral and central nervous systems [9]. IGF-1 is synthesized in peripheral tissues, primarily the liver, and is also found and synthesized in most parts of the central nervous system [10]. Insulin and IGF-1 are potent neurotrophic factors for neurons and glia during development but also regulate synaptic plasticity, neuronal survival, and protection in the adult brain. IGF-1 also regulates oligodendrocyte survival as well as myelination, and insulin modulates food intake, glucose homeostasis, and growth. The function of IGF-1 is also controlled by levels of IGF-1 binding proteins that are expressed in the brain and peripheral tissues. The receptors for insulin and IGF-1 have an intracellular tyrosine kinase domain, and binding leads to activation and autophosphorylation of the receptor. This in turn results in association with insulin receptor substrate (IRS-1) and activation of the PI-3K-Akt pathway or Shc/Ras-ERK and PLC- γ -PKC (Fig. 19.1).

19.2.2.4 Transforming Growth Factor- β (TGF- β). TGF- β and related family members are multifunctional growth factors that play a significant role in development as well as neuroprotection and repair in the adult brain [11, 12]. There are several subfamilies, including the TGF- β (1–5), activins/inhibins, bone morphogenic proteins (BMP1–13), growth differentiation factors, (GDF1–10), and glial-derived neurotrophic factor (GDNF, artemin, neurturin, and persephin) (Table 19.1). The general mechanism for activation of intracellular signaling is the association of the receptors with another protein that contains an intracellular kinase domain. In most cases this is a serine/threonine kinase. Activation and phosphorylation of the receptor-associated proteins leads to phosphorylation of Smad2 and Smad3, which together with Smad4 regulate gene transcription [13]. The GDNF family is more distantly related and the associated receptor, ret, is a tyrosine kinase associated protein that can lead to regulation of a similar set of intracellular cascades as discussed for other tyrosine kinases.

Recent studies demonstrate that antidepressant treatment increases the expression of activin β A and/or increases Smad2 phosphorylation [14]. Moreover, infusions of activin A into the hippocampus produce an antidepressant response in the behavioral models

of depression. These findings provide support for a role of TGF- β /activin in antidepressant responses and further studies of this interesting family of growth factors.

19.3 INFLUENCE OF STRESS ON NEUROTROPHIC AND GROWTH FACTORS

One of the most challenging issues in efforts to study the neurobiology of complex psychiatric illnesses is to develop good animal models. This is particularly true for mood disorders, where it is extremely difficult, if not impossible, to assess the emotional state of an animal. Although by no means perfect, studies of stress, which is known to precipitate or exacerbate depression and other disorders [15, 16], have been very useful and productive (see reviews in [16a–d]). Studies demonstrating that stress decreases neurotrophic factor expression in limbic brain regions associated with depression have played a key role in the formation of a neurotrophic hypothesis of depression. The relevance of these findings is highlighted by studies in depressed patients, opposing actions of antidepressant treatment, and behavioral studies of these factors (see Table 19.2 for a summary).

19.3.1 Influence of Stress on BDNF and Other Neurotrophic Factors

The first studies of stress were focused on the neurotrophic factor family, including NGF, BDNF, and NT-3. This was based largely on earlier studies demonstrating that the expression of these factors was very dynamic and regulated by a variety of stimuli. The studies of stress have focused on the hippocampus, a limbic brain region that has been implicated in mood disorders and that expresses high levels of receptors for adrenal glucocorticoid receptors. Smith and colleagues [23] were the first to report that exposure to stress causes a rapid and robust downregulation of BDNF in the hippocampus. Exposure to immobilization stress for only 1 to 2 h decreases the expression of BDNF in the dentate gyrus granule cell layer and the CA3 pyramidal cell layer, two subfields of the hippocampus that are influenced at the structural level by stress (see below). A similar effect of immobilization stress is observed in female rodents [17]. In addition to immobilization stress, BDNF expression is also decreased by chronic unpredictable stress [18], swim stress [19], footshock [20], and early maternal deprivation [21]. These studies provide evidence that stress could alter neuronal survival and function via regulation of neurotrophic factor expression.

Stress is also reported to influence the expression of other members of the neurotrophic factor family. Long-term immobilization stress (8 h) decreases the expression of NGF and NT-3 in the hippocampus [22]. This study also found decreased levels of the neurotrophic factor receptors TrkA, TrkB, and TrkC. In contrast, Smith and colleagues [23] did not observe a decrease in levels of NT-3 or the neurotrophic factor receptors. In fact, they reported that levels of NT-3 are increased in the hippocampus by repeated exposure to stress. Another study also reports that stress increases levels of NT-3 in locus ceruleus noradrenergic cell bodies [24].

19.3.2 Stress Can Lead to Long-Lasting Neurotrophic Factor Alterations

In addition to acute effects, exposure to stress can produce long-lasting changes in the expression of BDNF. This is demonstrated most effectively by studies at early

TABLE 19.2 Regulation of BDNF by Stress, Depression, and Antidepressant Treatment

Treatment	Effect
Rodent studies, hippocampus	
Stress	
Immobilization	Decrease
Footshock	Decrease
Unpredictable	Decrease
Social isolation	Decrease
Maternal deprivation	Decrease
Corticosterone ^a	Decrease
Antidepressant	
ECS	Increase
MAOI	Increase
SSRI	Increase
NESRI	Increase
TMS	Increase
Exercise ^b	Increase
Human studies	
Depression, postmortem hippocampus	
Depressed	Decrease
Depressed + antidepressant	Increase
Depression, blood	
Depressed	Decrease
Depressed + antidepressant	Increase

Abbreviations: ECS, electroconvulsive seizures; MAOI, monoamine oxidase inhibitor; SSRI, 5-HT selective reuptake inhibitor; NESRI, norepinephrine selective reuptake inhibitor; TMS, transcranial magnetic stimulation.

^aCorticosterone treatment which simulates stress levels of this adrenal glucocorticoid also decreases BDNF.

^bExercise is also reported to increase levels of BDNF and produces an antidepressant effect in models of depression.

postnatal time points. Animals exposed to early maternal deprivation (24 h on postnatal day 9) exhibit deficits in the expression of BDNF as adults [21]. Another postnatal maternal deprivation paradigm (3 h from days 2 to 14) is reported to decrease BDNF in the prefrontal cortex [19]. Early postnatal care (the amount of licking and grooming of pups) also regulates the expression of BDNF in the adult [25]. Exposure to a tone previously paired with a footshock decreases the expression of BDNF in the hippocampus [20]. These studies demonstrate how stress and prior experience can lead to long-term alterations in the expression of BDNF that could influence neuronal function and have consequences throughout the life of an animal (see below).

19.3.3 Mechanisms Underlying Regulation of BDNF by Stress

Stress can influence a number of endocrine, neurotransmitter, and cytokine systems that could contribute to the regulation of BDNF in the brain. This section provides a brief overview of the literature addressing this issue (see Fig. 19.2 for a summary).

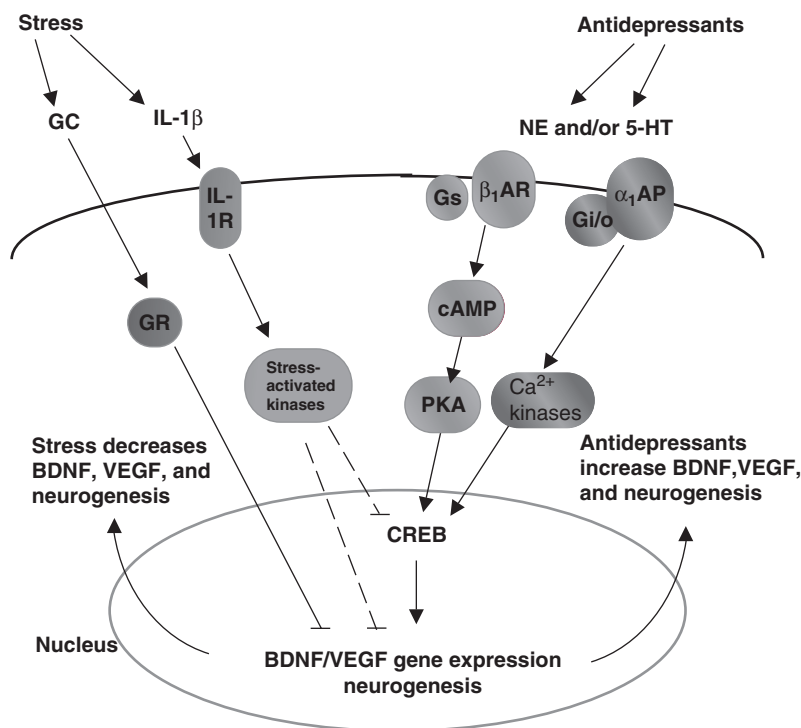

Figure 19.2 Mechanisms underlying regulation of BDNF and VEGF by stress and antidepressant treatment. The downregulation of BDNF and VEGF by stress occurs via elevated levels of glucocorticoids (GCs) and activation of the GC receptor (GR), which can directly regulate the expression of BDNF. Stress also increases levels of interleukin-1 β (IL-1 β), which can decrease BDNF, although the intracellular pathways responsible for this effect have not been determined (indicated by dashed lines). The role of GC and IL-1 β in the downregulation of VEGF has not been determined. In contrast, antidepressant treatment upregulates the cyclic adenosine monophosphate (cAMP) cascade, including cAMP-dependent protein kinase (PKA) and cAMP response element binding protein (CREB), which increases BDNF and VEGF gene transcription. CREB can also be phosphorylated by Ca²⁺-dependent kinases, such as Ca²⁺/calmodulin-dependent protein kinase. These kinases can be activated by NE and 5-HT receptors, including the β -adrenergic 1 (β_1 AR) and α_1 -adrenergic receptors and their respective G-protein subunits, the stimulatory (G_s) and inhibitory ($G_{i/o}$) G proteins. (See color insert.)

19.3.3.1 Adrenal Glucocorticoids. The hallmark endocrine response to stress is activation of the hypothalamic–pituitary–adrenal (HPA) axis, resulting in elevated levels of adrenal glucocorticoids. The receptors for glucocorticoids (GRs) as well as mineralocorticoids (MRs) are expressed in high levels in the hippocampus, and because of the lower affinity of GR only stress-induced levels of glucocorticoids activate the GRs. A role for glucocorticoids in the actions of stress is supported by studies demonstrating that administration of corticosterone, the rodent equivalent of human cortisol, decreases the expression of BDNF [23, 26, 27]. In contrast, removal of adrenal glands, where corticosterone is synthesized, leads to up-regulation of BDNF [26, 28]. However, the role of glucocorticoids in the action of stress appears to be more complicated. In adrenalectomized animals receiving a low dose of

corticosterone replacement exposure to stress still decreases BDNF expression [23], indicating that other factors are required for the effects of stress.

19.3.3.2 5-HT Receptors. Reports that acute stress increases serotonin neurotransmission have led to studies of the role of 5-HT receptors in the regulation of neurotrophic factors. Administration of a 5-HT₂, but not 5-HT₁, receptor agonist results in a rapid and robust downregulation of BDNF expression in the hippocampus of male [29] or female rats [17], similar to the effects of stress. The actions of a nonselective 5-HT₂ receptor agonist are blocked by a selective 5-HT_{2A}, but not by a 5-HT_{2C} antagonist [29]. In addition, 5-HT_{2A} receptor blockade reverses the downregulation of BDNF resulting from exposure to immobilization stress [29]. The cellular mechanisms underlying the regulation of BDNF by 5-HT_{2A} receptors can be explained by the presence of these receptors on GABAergic interneurons in the granule cell layer. Activation of these receptors increases GABA-mediated inhibitory postsynaptic potentials (IPSPs) in granule cells that could underlie a decrease in activity-dependent regulation of BDNF.

19.3.3.3 Cytokines: Interleukin-1 β (IL-1 β). Stress can also lead to alterations in levels of cytokines, most notably increased levels of IL-1 β , raising the possibility that the downregulation of BDNF is mediated by this cytokine (Fig. 19.1). This hypothesis is supported by a study demonstrating that administration of an antagonist of IL-1 β blocks the downregulation of BDNF in response to stress [30]. The actions of IL-1 β may also be explained by an effect on cell activity. IL-1 β decreases the release of glutamate as well as Ca²⁺ influx [31], which could lead to a reduction in the activity-dependent expression of BDNF in the hippocampus.

19.3.4 Influence of Stress on VEGF

A recent study has demonstrated that stress can also influence the expression of VEGF. VEGF is known primarily for regulation of endothelial cell proliferation and angiogenesis, but it also has neurotrophic and neuroprotective effects. In addition, VEGF increases adult neurogenesis in the hippocampus and has been implicated in the vascular niche hypothesis of adult neurogenesis [32]. For these reasons VEGF has been studied in models of stress as well as antidepressant treatment (see below). Exposure to chronic unpredictable stress (a combination of immobilization, swim stress, crowding or isolation, and vibration) decreases the expression of VEGF protein in the granule cell layer and hilar region of the hippocampus [33]. The expression of the VEGF receptor type 2 is also decreased in the granule cell layer and hilus in this chronic stress paradigm. The influence of stress on VEGF may be due to adrenal glucocorticoids, which downregulate the expression of VEGF as well as the type 2 receptor in certain tissues [34, 35]. Further studies will be required to determine if glucocorticoids underlie the stress-induced VEGF decrease in the hippocampus.

19.4 INFLUENCE OF STRESS ON ADULT NEUROGENESIS AND MORPHOLOGY

Altered neurotrophic factor expression as well as alterations of neuroendocrine and neurotransmitter systems could result in functional effects at the cellular level in

response to acute and chronic stress. In this section, the alterations in the proliferation of cells in the adult brain as well as morphological changes in dendrite formation are discussed, and the potential roles of neurotrophic factors in these responses to stress are examined. A more complete review of neurogenesis is provided in Chapter 20 of this volume as well as Chapter 7 in Volume III of this handbook.

19.4.1 Influence of Stress on Adult Neurogenesis

19.4.1.1 Neurogenesis in Adult Hippocampus. Although neurogenesis largely takes place during the developmental stage, there are two regions in the brain, the hippocampus and the subventricular zone, where new neuronal birth continues to take place into adulthood and even old age [36, 37]. In the hippocampus the neural progenitor cells are located in the subgranular zone between the granule cell layer and the hilus. These cells divide and give rise to cells that differentiate and mature into neurons that migrate into the granule cell layer of the hippocampus (Fig. 19.3). These newborn granule cells take on the appearance and function of mature granule cells over the course of four to eight weeks, sending axons to the CA3 pyramidal cell layer and dendrites to the molecular layer and exhibiting electrophysiological characteristics of mature granule cells [37]. Adult neurogenesis has been observed in a variety of animals, including humans, well into old age.

19.4.1.2 Stress Decreases Adult Neurogenesis. One of the most striking characteristics of adult neurogenesis in the hippocampus is the dynamic nature of this process. The rate of proliferation and/or the survival of newborn cells can be regulated in either a positive or negative manner by a variety of stimuli. For example, adult neurogenesis is increased by enriched environment, exercise, hippocampal-dependent learning, and antidepressant treatment (see below) [38, 39]. In contrast, treatment with drugs of abuse or exposure to stress decreases adult neurogenesis (see Fig. 19.3). The ability of adult neurogenesis to be up- or downregulated by positive and negative stimuli suggests that it is a form of neural plasticity that contributes to the mechanisms underlying long-term changes in the brain.

The downregulation of adult neurogenesis has been observed with several different types of stress [5, 16a], including intruder stress [40], predator stress [41], maternal separation stress [42], chronic mild stress [43], and footshock [44, 45]. This effect is observed in many different species, including mice, rats, tree shrews, marmosets, and rhesus monkeys, indicating that it is a widespread response to stress [5]. In the learned helplessness model of depression there is a long-lasting downregulation of adult neurogenesis after exposure to inescapable but not escapable stress that correlates with the behavioral despair in this model [44]. Moreover, antidepressant treatment reverses the neurogenesis deficit as well as the behavioral despair [44]. However, another study has reported that decreased neurogenesis does not correlate with behavior in the learned helplessness model [45]. The correlation between neurogenesis and behavioral responses is further discussed in Section 19.8.

19.4.1.3 Mechanisms Underlying Decreased Neurogenesis. The stress responsive HPA axis has also been implicated in the regulation of adult neurogenesis. Adrenal glucocorticoid administration decreases adult neurogenesis in the hippocampus [46] and adrenalectomy blocks the downregulation of neurogenesis in response to stress

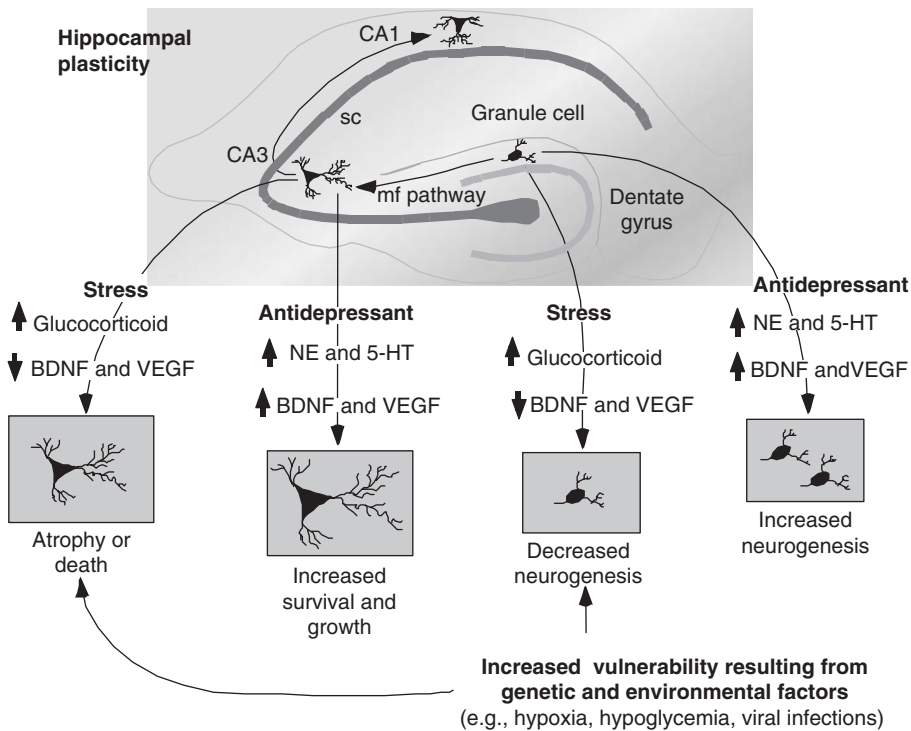

Figure 19.3 Influence of stress and antidepressant treatment on hippocampal plasticity: Regulation of adult neurogenesis and neuronal remodeling/atrophy. Exposure to stress can lead to at least two distinct cellular events in the hippocampus: a decrease in the number and length of apical dendrites of CA3 pyramidal cells and a decrease in the proliferation of new neurons in the granule cell layer. In contrast, antidepressant treatment can block or reverse the effects of stress and increase neurogenesis in the granule cell layer of adult hippocampus. The effects of stress are mediated by elevated levels of adrenal glucocorticoids and activation of *N*-methyl-D-aspartate (NMDA) receptors (not shown). Downregulation of BDNF and VEGF may also contribute to the deleterious effects of stress. The actions of antidepressant treatment are thought to occur via increased levels of NE and 5-HT, which in turn lead to increased levels of BDNF and VEGF. (See color insert.)

[5, 16a, 41]. There are several neurotransmitters or factors that could be acting downstream of glucocorticoids. Activation of *N*-methyl-D-aspartate (NMDA) excitatory amino acid receptors decreases and NMDA receptor antagonists increase adult neurogenesis [47, 48].

As discussed earlier, both BDNF and VEGF are decreased by stress and adrenal glucocorticoids and could contribute to the downregulation of neurogenesis that occurs after exposure to stress (Fig. 19.3). Infusions of BDNF into the lateral ventricles increase neurogenesis in a number of brain structures, but there is no increase in the hippocampus [49, 50]. This could be due to insufficient diffusion of BDNF to the hippocampus. Viral expression or infusions of recombinant VEGF increase adult neurogenesis in the hippocampus [51, 52]. Additional studies will be needed to determine if BDNF and/or VEGF can rescue the downregulation of

neurogenesis that occurs in response to stress. The role of these factors in the actions of antidepressant treatment is also discussed below.

19.4.2 Influence of Stress on Glial Proliferation

In addition to regulation of neurogenesis in adult hippocampus, stress also influences the proliferation of glia. This may be relevant to the neurobiology of depression because of the reports of decreased glia in the prefrontal cortex and other limbic structures of depressed patients (see below). Exposure to repeated unpredictable mild stress (14 days) but not acute stress decreases the number of newborn cells in the prefrontal cortex of adult rats (G. Valentine, M. Banasr, and R. S. Duman, Yale University, November 2006, unpublished data). Newborn cells in the prefrontal cortex express markers of oligodendrocytes and endothelial cells as well as a population of unidentified cells. Under the conditions of these studies there were no newborn cells in the cerebral cortex expressing neuronal markers. A previous study has demonstrated that chronic administration of corticosterone decreases glial proliferation in brain [53], suggesting that increased glucocorticoid levels underlie the decrease in cell proliferation observed in the prefrontal cortex.

19.4.3 Influence of Stress on Neuronal Morphology

The regulation of neuronal morphology, including alterations in the number and length of neuronal processes, represents another form of structural plasticity in the nervous system, and stress is reported to alter the length of neuronal dendrites. Chronic restraint stress (18 days) decreases the number and length of the apical dendrites of the CA3 pyramidal neurons in the hippocampus ([54]; also see [16a]) (Fig. 19.3). This atrophy is reversible over the course of several weeks when the animals are no longer exposed to stress. Chronic administration of corticosterone produces a similar effect, indicating that the effects of stress occur via increased levels of adrenal glucocorticoids [16a]. In addition, blockade of NMDA receptors blocks the atrophy of CA3 pyramidal cells, suggesting a role for glutamate and this receptor subtype. The atrophy of hippocampal neurons in combination with decreased neurogenesis could contribute to the reduction in hippocampal volume observed in depressed patients.

19.5 NEUROTROPHIC FACTORS IN DEPRESSED PATIENTS

The results of rodent studies demonstrate that the expression of BDNF is decreased by stress and increased by antidepressant treatment, contributing to a neurotrophic hypothesis of depression. This section reviews the clinical studies in humans, in both postmortem brain tissue and blood, designed to directly test this hypothesis (see Table 19.2 for a summary). BDNF has been the focus of the majority of these studies, but it will be interesting to examine other neurotrophic and growth factors in future studies.

19.5.1 Levels of BDNF in Postmortem Tissue

The most direct approach to test the neurotrophic hypothesis is to analyze levels of BDNF in the brains of depressed patients. Unfortunately this can only be done in

postmortem tissue, which presents many limitations, including the number of patients that can be analyzed, the appropriate controls, and the interpretation of results with regard to the state or trait effects in each subject, to mention a few. However, there are now a number of postmortem studies demonstrating that levels of BDNF in the hippocampus are decreased in depressed suicide subjects relative to matched controls, or an increase in patients receiving antidepressant medication at the time of death [55–57]. One of these studies reports a similar effect in the prefrontal cortex [57]. There is also a report that one of the key BDNF-TrkB signaling kinases, ERK, is decreased in depressed patients [58].

Decreased expression of BDNF in the hippocampus and/or prefrontal cortex of depressed subjects is consistent with a neurotrophic hypothesis of depression. This decrease could be due to the stress associated with depression and sustained activation of the HPA axis. However, further studies will be needed to confirm this decrease in additional postmortem subjects and to examine the specificity of this effect to depression. There is also a report of decreased BDNF levels in prefrontal cortex of schizophrenic patients [59], suggesting that the downregulation of BDNF is not specific to depression. However, this study did not report on levels of BDNF in the hippocampus and it is possible that there are region-specific effects in different psychiatric illnesses.

19.5.2 Levels of BDNF in Serum

BDNF levels in serum are much easier to assess and can be conducted in living subjects. However, a major limitation of this approach is the relevance of BDNF in blood to levels in brain. Nevertheless, due to the compelling preclinical studies as well as brain imaging studies demonstrating reduced brain volume in depressed patients, there has been an interest in examining serum levels of BDNF. Serum BDNF in depressed patients is significantly reduced relative to matched controls, and there is a significant negative correlation with the severity of depression [60, 61]. Moreover, more recent studies have demonstrated that antidepressant treatment can either partially [62] or completely [63, 64] reverse the deficit in serum levels of BDNF in depressed patients. In a study of healthy volunteers serum BDNF is associated with depression-related personality traits [65]. Further studies will be required to determine if decreased BDNF in blood is a phenotypic marker of depression and to determine the functional relevance of altered blood levels of BDNF.

To examine the mechanisms underlying decreased serum BDNF levels in plasma, serum and blood have been determined. The major source of BDNF is platelets, although it is also stored in endothelial cells and lymphocytes. Levels of BDNF are decreased in serum and plasma but not in blood, and there is no increase in a marker of platelet activation [57]. The interpretation of these findings is that the decreased serum BDNF is related to altered mechanisms of BDNF release from platelets and not BDNF synthesis. Although speculative, it is possible that there are similar problems with the release of BDNF from neurons in the brain. However, this study does not rule out the possibility that elevated adrenal glucocorticoids or second-messenger signaling also plays a role in decreased BDNF levels in the blood.

19.5.3 Levels of FGF in Postmortem Tissue

Microarray analysis has also demonstrated alterations of the FGF system in postmortem tissue from depressed patients [66]. This study reports that the expression of several members of the FGF family, including FGF1, FGF2, and the receptors FGFR2 and FGFR3, are decreased in the dorsal lateral prefrontal cortex (DLPFC) and/or the anterior cingulate cortex of depressed patients. The effects appear to be most significant in the DLPFC where the downregulation of FGF1, FGFR2, and FGFR3 is observed in two small but separate cohorts and confirmed by reverse transcriptase polymerase chain reaction (RT-PCR). These findings are interesting in light of preclinical studies demonstrating that antidepressant treatment upregulates FGF2 in cerebral cortex and hippocampus (see below). Additional studies will be necessary to determine if similar alterations are observed in other tissue banks of depressed subjects.

19.6 STRUCTURAL AND CELLULAR ALTERATIONS IN DEPRESSED PATIENTS

A decrease in levels of neurotrophic factors could result in a reduction in the volume of certain brain structures as well as a decrease in cell number and altered morphology. Brain imaging and postmortem studies have addressed this question and provide additional evidence that is consistent with a neurotrophic hypothesis of depression. However, a direct causative relationship between neurotrophic factors and brain volume and cell morphology has not been established, and additional studies are needed to confirm these findings in depressed patients.

19.6.1 Brain Imaging Studies of Depressed Patients

Imaging studies of the hippocampus report a reduction in volume in patients with depression [67–76]. There are also negative reports, although specific measurements of hippocampus were not conducted, included the amygdala, or found altered hippocampal shape [77–79]. The magnitude of the reduction has been directly related to the length of illness [73], and antidepressant treatment reduces or even reverses the atrophy of hippocampus [72, 76]. The volume of hippocampus is also decreased in patients with posttraumatic stress disorder (PTSD) [80–84], and further studies are needed to determine if there are factors that distinguish the hippocampal changes in these two disorders.

Volumetric alterations are not limited to the hippocampus, as there are also reports of decreased volumes of the prefrontal cortex [85] and the amygdala [86], brain regions linked to altered mood, anxiety, and cognition in depressed patients. Although there is less known about the mechanisms underlying the altered volume of prefrontal cortex and amygdala, there are a number of postmortem studies examining these regions (see below).

19.6.2 Postmortem, Morphometric Studies of Depressed Patients

Although there has been extensive examination of hippocampus by brain imaging, there are relatively few studies at the cellular level. There are reports of no gross

change in cellular morphology in the hippocampus, although semiquantitative methods were used [87, 88]. Another recent study has found an increase in the density of neurons and glia in the major subfields of hippocampus, including the CA1 and CA3 pyramidal cell layers and the dentate gyrus granule cell layer, but a decrease in the size of neuronal cell bodies [89]. One possible interpretation of these findings is that the increase in cell density results from a decrease in neuropil and that this leads to a decrease in hippocampal volume. This possibility is supported by reports of decreased neuronal spine density and reduced arborization of apical dendrites in the subiculum of patients with bipolar disorder or depression [90]. Another study has reported decreased levels of synaptic proteins in the CA4 pyramidal cell layer of patients with bipolar depression [91]. Additional studies of the hippocampus and other brain structures will be needed to further define the cellular abnormalities underlying decreased hippocampal volume in depressed patients.

Studies of the prefrontal and other cortical structures have been more consistent and demonstrate a reduction in the density of glia and size of neurons. Postmortem studies from multiple laboratories have demonstrated a decrease in glial density in the dorsal lateral prefrontal cortex [92, 93], cingulate cortex [94], subgenual prefrontal cortex [95], and amygdala [96, 97]. In addition, these studies have provided evidence of a reduction in the size of neuronal cell bodies, which could result from loss of metabolic and/or neurotrophic support that is provided by glia. These effects could contribute to the reduction in the volume of the cortical regions observed in depressed patients.

19.7 GENETIC STUDIES OF BDNF IN MOOD DISORDERS

The basic research and clinical studies of BDNF as well as imaging and cell morphology studies have stimulated interest in the analysis of the BDNF gene and psychiatric illnesses. A functional polymorphism has been identified that encodes a variant of BDNF at codon 66 (*val66met*) [98]. The *met* allele results in abnormal intracellular packaging and secretion of BDNF and carriers of this allele have poorer episodic memory and lower hippocampal *N*-acetyl aspartate [98]. However, the association of the *val66met* alleles with psychiatric illness has been inconsistent. The BDNF *val* allele has been identified as a potential risk locus for bipolar disorder [99–101]. In addition, decreased hippocampal volume has been observed in bipolar patients that carry the substitution (H. Blumberg, Yale University, November 2006, personal communication). However, this association has not been observed in studies conducted in Asian populations [102, 103].

Another study of childhood-onset mood disorder did not find an association with the BDNF *val66met* alleles but did find an association with a dinucleotide repeat [104]. Another single-nucleotide polymorphism has been identified in the BDNF promoter I that results in decreased DNA binding and reduced basal promoter activity [105]. This low-activity allele was associated with reduced anxious temperament and therefore may be protective against anxiety and related illnesses. This study also reports an association of the *met66* allele with increased risk for anxiety [105]. Together these results demonstrate how the presence of different alleles can complicate the genetic analysis of BDNF polymorphisms. Additional studies will be required to further investigate the role of these as well as other novel BDNF polymorphisms in depression and other mood disorders.

19.8 INFLUENCE OF ANTIDEPRESSANT TREATMENT ON NEUROTROPHIC FACTOR EXPRESSION

In addition to studies of stress and depression, reports that antidepressant treatments upregulate levels of BDNF and other neurotrophic/growth factors have contributed to a neurotrophic hypothesis (see Table 19.2). The influence of antidepressant treatment on expression of these factors is reviewed in this section.

19.8.1 Antidepressant Treatment Increases the Expression of BDNF

Chronic administration of different classes of antidepressants is reported to increase levels of BDNF expression in the hippocampus and in some cases the cerebral cortex [106, 107]. In general the upregulation of BDNF is dependent on chronic treatment, consistent with the time course for the therapeutic response to antidepressants, and is not observed after single acute drug administration. Different classes of antidepressants, including ECS, 5-HT and NE selective reuptake inhibitors, MAOIs, and atypical antidepressants, increase BDNF expression. It is also notable that other types of treatments that have antidepressant effects, including transcranial magnetic stimulation [107a], AMPAkinetics [107b], NMDA antagonists [107c] and exercise [107d–107g], also increase the expression of BDNF. These findings are consistent with postmortem and blood studies demonstrating an increase in levels of BDNF in depressed subjects that are being treated with an antidepressant [107h–107j].

In contrast, repeated administration of non-antidepressant drugs, including cocaine or morphine, does not increase BDNF expression in the hippocampus, demonstrating the pharmacological specificity of antidepressant regulation of BDNF [107]. The typical antipsychotic haloperidol decreases BDNF, while the atypical antipsychotics clozapine and risperidone, which are known to enhance the clinical efficacy of SSRI antidepressants, increase BDNF in the hippocampus [107–109].

Although antidepressant induction of BDNF has been confirmed in a number of studies, there are reports that are inconsistent depending on the type of treatment tested. ECS and MAOI antidepressants have been found to consistently upregulate BDNF expression in the hippocampus [107e, 109a–109h]. Most of these studies have also found that 5-HT or NE selective reuptake inhibitors increase BDNF expression, but there are also a few studies that have not observed an increase with selective reuptake inhibitors [110, 111]. Similarly, mixed results have been observed with atypical antidepressants such as mianserin and tianeptine [109a, 109c, 111a].

There are a number of potential explanations for the variations that have been observed. The most likely possibilities are the length of drug treatment [110, 112, 113] and/or the dose of antidepressant used (see [113a]). The latter study found that a moderate dose of antidepressant (5 mg/kg, venlafaxine or amitriptyline) increased BDNF expression, but a higher dose (10 mg/kg) of these drugs did not [114]. The expression of BDNF is activity dependent and dynamically regulated by a variety of stimuli, and interactions of antidepressants with other environmental factors could also contribute to the outcome of drug studies. Therefore, care must be taken when designing and conducting drug studies of BDNF expression in animals.

19.8.2 Mechanisms for Regulation of BDNF

The regulation of BDNF by ECS and different classes of antidepressants indicates that there could be multiple receptor signaling pathways that regulate BDNF gene

expression. The induction by ECS can be explained by activity-dependent regulation of BDNF following neuronal depolarization and Ca^{2+} -activated signal transduction [115]. Ca^{2+} signaling leads to activation of calcium/calmodulin-stimulated protein kinase and activation of CREB. CREB is a transcription factor that can bind to cAMP response elements located on BDNF exon-specific promoters (I and III), and phosphorylation of CREB stimulates gene transcription. The BDNF gene is comprised of a total of four exon-specific promoters (I–IV) as well as one coding BDNF (exon V), and the regulatory elements of the other three promoters have not been characterized.

The influence of antidepressants that regulate synaptic levels of 5-HT and NE can also be explained by the regulation of CREB (Fig. 19.2). Chronic administration of other classes of antidepressants, including 5-HT and NE selective reuptake inhibitors and MAOIs, increase the phosphorylation and function of CREB as well as elements of the cAMP signal transduction cascade (i.e., cAMP-dependent protein kinase) that can stimulate CREB [106, 116, 117]. Additional evidence for a role of the CREB cascade is provided by studies demonstrating that rolipram, a putative antidepressant that inhibits cAMP metabolism, upregulates CREB and BDNF expression [106]. In addition, antidepressant induction of BDNF is blocked in CREB $\alpha\Delta$ mutant mice [118].

19.8.3 Antidepressant Treatment Influences Other Neurotrophic Factor Systems

The function and survival of neurons in the adult brain are influenced by a number of neurotrophic and growth factor systems in addition to BDNF. The neurotrophic hypothesis of depression has been extended by studies of some of these factors (see Table 19.3). Stress is reported to downregulate the expression of VEGF in the hippocampus, and this factor is increased by ECS [119, 120]. We have also found that VEGF expression is increased by chemical antidepressants and that VEGF produces antidepressant effects in behavioral models (J. Warner-Schmidt and R. S. Duman, Yale University School of Medicine, 2006, unpublished data).

Another family of factors that has been implicated in depression is FGF. Post-mortem microarray analysis has reported altered expression of FGF and FGF receptors in depressed patients [66]. Preclinical studies demonstrate that chronic antidepressant treatment, including 5-HT and NE selective reuptake inhibitors, increases the expression of FGF2 in the hippocampus and entorhinal cortex [121]. In

TABLE 19.3 Regulation of Neurotrophic/Growth Factors by Stress and Antidepressant Treatment and Influence of These Factors on Behavioral Models of Depression and Adult Neurogenesis

Factor	Stress	Antidepressant Treatment	Behavior	Neurogenesis
BDNF	Decrease	Increase	Antidepressant	Increase
VEGF	Decrease	Increase	Antidepressant	Increase
FGF2	NA	Increase	NA	Increase
IGF-1	NA	NA	Antidepressant	Increase
Activin	NA	Increased	Antidepressant	NA

Note: The influence of stress (column 2) or antidepressant treatment (column 3) on the expression of each neurotrophic/growth factor is indicated (decrease or increase). The influence of neurotrophic/growth factors on behavioral models of depression or adult neurogenesis is indicated in the last two columns. Antidepressant indicates that the factor produces an antidepressant-like response. NA, not analyzed

addition, the coadministration of an SSRI with an atypical antidepressant, a combination that has proven effective for treatment-resistant depressed patients, results in a greater induction of FGF2 than with either treatment alone [122]. The regulation of FGF2 could also play a role in the regulation of adult cell proliferation (see below).

There are a number of other factors that are regulated by antidepressant treatment and that have been implicated in depression, including glial cell–derived neurotrophic factor [123], activin [14], and IGF [124]. Additional studies are necessary to further test the role of these factors in depression and the response to antidepressant treatments. Moreover, the possible interaction of these factors in cellular and behavioral models must be examined.

19.9 INFLUENCE OF ANTIDEPRESSANT TREATMENT ON ADULT NEUROGENESIS

Downregulation of adult neurogenesis by stress and decreased hippocampal volume in stress-related illnesses suggest that alterations of the numbers of neurons and glia contribute to the pathophysiology and treatment of these disorders. Recent studies support this hypothesis and examine the mechanisms underlying the regulation of adult neurogenesis (see Fig. 19.3).

19.9.1 Antidepressant Treatment Increases Adult Neurogenesis

Studies of antidepressants support the hypothesis that the therapeutic effects of these agents may occur at least in part via upregulation of adult neurogenesis (see [2, 38]). Chronic but not acute antidepressant treatment increases the number of newborn cells in the adult hippocampus, and this effect is observed with different chemical classes of antidepressants [125–128]. Antidepressant treatment can reverse or block the effects of stress on adult neurogenesis [44, 129–131]. Adult neurogenesis is also upregulated by other treatments that have antidepressant effects, including exercise (see [38]).

A direct link between neurogenesis and antidepressant response has also been examined. Blockade of antidepressant induction of adult neurogenesis, either by focused irradiation or in 5-HT_{1A} mutant mouse, results in blockade of the behavioral effects in models that are responsive to antidepressant treatment (i.e., novelty suppressed feeding and chronic mild stress) [128]. There is no effect of decreased neurogenesis on basal responding in these tests, indicating that neurogenesis is required for an antidepressant response but that reductions are not sufficient to produce a depressive-like phenotype. This suggests that the effect of stress must include additional neurochemical and cellular effects that are required to produce depression in these animal models. Alternatively, it is possible that the animal models available and the underlying cellular mechanisms that influence behavior do not accurately reflect mood disorders in humans.

19.9.2 Mechanisms Underlying Antidepressant Regulation of Adult Neurogenesis

The investigation of adult neurogenesis is an area of tremendous interest and potential and could lead to the development of pharmacological agents that directly

and specifically control cell proliferation and survival. This information would have multiple applications for neurological disorders as well as psychiatric illnesses such as depression. A significant number of studies have been focused on neurotrophic/growth factors, including several of those implicated in depression (see Table 19.3 and Fig. 19.3). For example, infusions of BDNF into the lateral ventricles increase neurogenesis in adjacent brain regions but not in the hippocampus [49, 50]. A study of BDNF(+/−) mice reports that BDNF is necessary for basal rates of proliferation in the hippocampus, [132] although another study of mutant mice did not find effects on proliferation but rather found evidence that BDNF enhances the survival of newborn neurons in the hippocampus [133].

Studies of VEGF have also been very interesting, as this factor has been demonstrated to increase neurogenesis in the adult hippocampus [51, 52, 134]. Peripheral VEGF is required for the upregulation of adult neurogenesis by exercise [135]. Moreover, recent studies demonstrate that blockade of VEGF signaling blocks the induction of neurogenesis by ECS and fluoxetine administration (J. Warner-Schmidt and R. S. Duman, Yale University School of Medicine, November 2006, unpublished data). Other factors that are known to regulate adult neurogenesis and that could play a role in the actions of antidepressant treatment include FGF2 and IGF1 [136–138]. Cotreatment with both FGF2 and IGF1 is required for maximal stimulation of the proliferation of cultured progenitor cells [139]. It is possible that a similar coordinated interaction of these or other factors may be necessary for antidepressant regulation of neurogenesis. Additional studies will be required to test this hypothesis and the role of these factors.

19.9.3 Influence of Antidepressant Treatment on Glial Proliferation

Glia make up a significant percentage of the cells in the brain and provide metabolic and structural support for neurons. Stress decreases the number of glia in the prefrontal cortex and a decrease in glia has been reported in postmortem tissue from depressed patients. In contrast, chronic antidepressant treatment increases the proliferation of glia in the prefrontal cortex. This includes ECS and fluoxetine as well as the atypical antipsychotic olanzapine [140, 141]. Newborn glia in the prefrontal cortex express markers of oligodendrocytes and endothelial cells, as well as an unidentified population of cells, but not astrocytes. Endothelial proliferation is also increased by ECS in the hippocampus and amygdala [142, 143].

These findings suggest that antidepressant treatment could reverse the effects of stress and depression on glial proliferation in the prefrontal cortex as well as neurogenesis in the hippocampus. The role of neurotrophic/growth factors in the regulation of glial proliferation remains to be determined.

19.9.4 BDNF Increases Sprouting of 5-HT Neurons

Another interesting effect of BDNF that is relevant to the actions of antidepressants and depression is the regulation of the 5-HT neurotransmitter system. This was first demonstrated by studies showing that infusions of BDNF have a significant effect on the sprouting of either 5-HT neurons, either intact or neurotoxin lesioned [144, 145]. BDNF resulted in increased sprouting of 5-HT axons when infused into either the cerebral cortex or the hippocampus. These findings demonstrate that BDNF can influence growth of intact 5-HT neurons and the survival and recovery of damaged

5-HT neurons. Together with studies demonstrating antidepressant regulation of BDNF, these results demonstrate a reciprocal interaction between the BDNF and 5-HT that could be necessary for the normal function of neurotrophic factor and neurotransmitter signaling in the brain. It is possible that alterations of either factor could be sufficient to produce effects on the other and thereby lead to altered neuronal and behavioral consequences. This could explain either a loss of function if BDNF or 5-HT signaling is decreased or increased function when these systems are positively regulated. Dysregulation of BDNF and 5-HT interactions could also account for certain aspects of neuronal dysfunction in aging [146].

19.10 BEHAVIORAL EFFECTS OF NEUROTROPHIC FACTORS

The opposing actions of stress/depression and antidepressant treatment on neurotrophic factor expression provide strong correlative evidence for a role of these factors in the pathophysiology and treatment of mood disorders. To directly test this hypothesis, investigators have utilized a combination of approaches to either increase or block neurotrophic factor levels and signaling in limbic brain structures (see Table 19.3).

19.10.1 Influence of BDNF in Models of Depression

Behavioral studies of BDNF have provided direct evidence that this neurotrophic factor is sufficient and necessary for an antidepressant response. Infusions of recombinant BDNF into the midbrain [147], hippocampus [148], or lateral ventricles [124] produce robust antidepressant effects in the forced-swim test and/or learned helplessness paradigms. Infusion of NT-3 but not NGF into the hippocampus also produces an antidepressant response, possibly due to the activity of NT-3 for TrkB receptors [148].

A requirement for BDNF and TrkB receptors in the actions of antidepressant treatment in the forced-swim test has also been demonstrated using BDNF(+/-) and TrkB dominant-negative mutant mice [149]. Similar effects were observed in inducible/conditional BDNF mutant mice in the forced-swim test [150]. There was no effect of BDNF mutation or blockade on basal behavior in the latter studies or another study in BDNF(+/-) mice [151] suggesting that decreased BDNF signaling may not be sufficient to produce a depressive phenotype. Another study did observe a helpless phenotype in BDNF(+/-) mice, although this finding is complicated by the increased pain sensitivity in these mice [69]. The viability of constitutive BDNF(-/-) mice is significantly reduced, making it difficult to examine complete null mutants.

One possible explanation for these effects is that partial deletion of BDNF (i.e., constitutive +/- or conditional in forebrain regions) is not sufficient to produce a depressive phenotype. It is also possible that reduced BDNF signaling is not sufficient to produce a depressive phenotype but that it is a risk factor for depression. This possibility is supported by studies demonstrating that exposure of BDNF(+/-) mice to stress or blockade of intracellular signaling pathways activated by BDNF results in a depressive phenotype on the forced-swim test [152]. Further studies will be required to test this hypothesis.

19.10.2 Influence of Other Factors in Models of Depression

Investigations of other neurotrophic factors in models of depression and antidepressant treatment have been initiated. The antidepressant effects of activin [14] and VEGF (J. Warner-Schmidt and R. S. Duman, Yale University School of Medicine, November 2006, unpublished data) have been mentioned, and more recent studies have demonstrated effects of IGF-1. Infusions of IGF-1 into the lateral ventricles are reported to have antidepressant effects in the forced-swim test [124] (Table 19.3). These findings provide evidence that additional neurotrophic/growth factors are capable of influencing responses in behavioral models and warrant further investigations.

19.11 SUMMARY AND CONCLUSIONS

The basic research and clinical studies discussed in this review demonstrate that neurotrophic factor expression is altered by stress and depression and that this deficit is reversed by antidepressant treatment. Upregulation of neurotrophic factors could block or reverse the atrophy and cell loss resulting from stress/depression and thereby contribute to the actions of antidepressant treatment. Additional postmortem studies are needed to further characterize the types of morphological changes that underlie the atrophy of limbic brain structures and to identify the cell types that are affected in depressed patients. Identification of the molecular changes that underlie these morphological alterations will also be necessary. Microarray gene chip analysis is already proving useful in addressing this issue as well as in further characterizing the gene expression changes that occur in response to stress and antidepressant treatments in rodent models. These studies will be important to further test the validity of the neurotrophic hypothesis of depression. Moreover, further identification of the molecular mechanisms underlying the actions of stress and antidepressant treatment will be crucial for elucidation of the pathophysiology and treatment of depression and related mood disorders.

Major depressive disorder (MDD) is a debilitating psychiatric illness affecting up to 20% of the U.S. population. Early onset and high prevalence have made MDD a public health concern throughout the world [1]. Depressed mood, inability to experience enjoyment, and neurovegetative symptoms often render affected individuals unable to engage in their social and occupational roles. Human genetic studies revealed that depression has a heritable component with roughly 40–50% of the risk attributable to genetic factors [2]. The remainder of the risk can be attributed to environmental factors such as insult to the developing brain and/or some forms of psychosocial stress [3]. There are multiple highly effective treatments for depression. Psychosocial treatments focus on the perceptions of stress, stress prevention, and coping mechanisms, whereas most effective pharmacological treatments modulate

monoamines in the brain. Numerous research efforts to understand the mechanisms by which psychotherapy and pharmacotherapy treat depression have resulted in the respective “stress” and “monoamine” hypotheses of depression (reviewed in [2]). This chapter will focus on recent findings that stress and monoamine hypotheses of depression converge in their opposing impact on adult hippocampal neurogenesis.

20.1 MONOAMINES AND DEVELOPMENT OF ANTIDEPRESSANTS

Pharmacological treatment of depression was fundamentally altered in the 1950s with two clinical observations. First, treatment with iproniazid, a monoamine oxidase inhibitor commonly used to treat tuberculosis, led to euphoric experiences in tuberculosis patients. The second observation followed discovery efforts in antipsychotic pharmacotherapy. Imipramine, which inhibits the reuptake of synaptic norepinephrine, serotonin, and histamine, was noted to benefit only schizophrenic patients who were also depressed. These serendipitous clinical observations led to the development of the “monoamine hypothesis” of major depressive disorder [4–7]. Almost 50 years later, selective and nonselective inhibitors of norepinephrine (NE) and serotonin (5-HT) reuptake form the mainstay of antidepressant pharmacotherapy. Despite the excellent efficacy of serotonin reuptake inhibitors (SRIs) and norepinephrine reuptake inhibitors (NRIs), many patients remain refractory to antidepressant treatment. Moreover, the desired antidepressant effect of SRIs and NRIs is often accompanied by undesirable side effects, such as sexual dysfunction, gastrointestinal discomfort, and weight gain. Also, all SRIs and NRIs share a delay in onset of action, which can last several weeks to months. Greater target specificity thus became the strategy to decrease these undesirable properties of antidepressant medications.

Modulation of specific monoamine receptor subtypes took center stage among newer antidepressant strategies. For instance, activating the inhibitory 5-HT_{1A} autoreceptors and inhibiting the stimulatory 5-HT₂ receptors was explored. These strategies resulted in part based on observations that 5-HT_{1A} receptors are decreased and 5-HT₂ receptors are increased in brains from depressed individuals [8], and several compounds acting at the 5-HT_{1A} or 5-HT₂ receptors have been approved for antidepressant use and may show clinical efficacy. However, these and other approaches for developing 5-HT receptor-specific antidepressant therapies yielded mixed clinical results, with the newer drugs not being used as widely as the older reuptake inhibitors.

One of the clinical strategies for using 5-HT_{1A} antagonists has been to augment SRI treatment by decreasing the latency of antidepressant response. Delayed onset of action is a phenomenon shared by almost all classes of antidepressants and belies a simple deficit model of depression. While antidepressants alter synaptic concentrations of monoamines within minutes to hours following administration, the accepted onset of clinical action for this class of medications is on the order of weeks to months. One proposed hypothesis for the delayed onset of action by SRIs was that stimulation of presynaptic inhibitory 5-HT_{1A} receptors (from SRI-induced synaptic 5-HT) resulted in a decrease in 5-HT release into the synapse [9]. Some argued that the delay in the onset of action occurs because the clinical effect of SRIs is not achieved until a desensitization of 5-HT_{1A} receptors takes place [10]. There is some preliminary clinical evidence suggesting that 5-HT_{1A} receptor-specific compounds may hasten the

onset of SRI action (reviewed in [11]). However, clinical results have been underwhelming and such augmentation strategies have not received broad enthusiasm from the clinical community. Thus, even if 5-HT_{1A} desensitization accounts for some of the mechanism underlying delayed onset of antidepressant action, the strictly biochemical explanations remained unconvincing.

20.2 HIPPOCAMPUS AND DEPRESSION

Another hypothesis for the delayed onset of antidepressant action is that this delay may represent a period of time necessary for plastic structural changes to form and accumulate in the treated brain. Research looking at the possibility that structural changes are necessary for response to antidepressants has focused on the hippocampus.

The hippocampus is a bilateral structure located on the medial surface of the temporal lobes running along the anterior–posterior axis in humans and septotemporal and dorsoventral axes in rodents (Figs. 20.1 and 20.2a). Input to the hippocampus comes largely from the parahippocampal gyrus, which is rich in inputs from most regions of the brain. The information is then processed and transmitted through the dentate gyrus and along a trisynaptic circuit. Hippocampal outputs terminate in both cortical and subcortical structures, including rich projections to the amygdala, anterior cingulate cortex, frontal cortex, and hypothalamus, and to the neocortex via reciprocal fibers running through the parahippocampal structures [12]. Most of the areas mentioned above have also been implicated in major depressive disorder [2].

There have been multiple findings that hippocampal volume is reduced in patients with unipolar depressive disorder (reviewed in [13]). Using volumetric magnetic

resonance imaging (MRI) analyses, several groups have demonstrated that hippocampal volume is inversely proportional to the number of days that individuals were depressed [14–16]. Changes in hippocampal volume also occur in other psychiatric disorders, illustrating the unique plasticity of this limbic structure in response to environmental influences. Some of the documented hippocampal functions include a critical role in short-term memory, depression, and psychosis [17]. Recent studies of hippocampal function have focused on its role as a novelty detector [18] and underscore the role of the hippocampus in the brain's interaction with the external environment.

Perhaps the best-documented relationships between experience and hippocampal volume are the changes in hippocampal volume produced by psychosocial stress. An extensive body of literature documents that adrenal hormones [19] mediate hippocampal sensitivity to psychosocial stress. Neurons throughout the hippocampus express receptors for both glucocorticoids (GRs) and mineralocorticoids (MRs) [20]. Glucocorticoids and mineralocorticoids are released by the adrenal glands in response to environmental stress. In response to chronic stimulation by adrenal hormones, remodeling of the hippocampal neuropil is observed as both decreased structural complexity of CA3 dendritic arbors and a decrease in neurogenesis in the subgranular zone of the dentate gyrus. Concurrently, hippocampal volume decreases. The effect of stress on the hippocampus has been linked to GRs using pharmacological means as well as through studies on transgenic animals. Thus, psychosocial stress results in hippocampal changes, and GRs mediate this phenomenon.

20.3 STRESS AND MONOAMINE HYPOTHESES OF DEPRESSION CONVERGE

Several recent genetic findings provide correlative support for the convergence of stress and monoamines. Caspi and colleagues elegantly demonstrated that a functional polymorphism in the noncoding region of the gene for the 5-HT transporter (5-HTT) conferred increased risk for MDD only in people who suffered multiple stressful life events [21]. Caspi's important observation was recently replicated in another cohort [22]. Conversely, Binder and colleagues reported that a functional polymorphism in a stress-response gene predicted response of depression to monoamine modulators [23]. Chronically elevated cortisol and defective dexamethasone suppression is a reliable finding in some people with MDD [24]. Binder et al. demonstrated that a functional single-nucleotide polymorphism in a gene encoding the glucocorticoid receptor cochaperone FKBP5 predicted a more rapid response to treatment with monoamine-modulating antidepressants. Furthermore, the FKBP5 polymorphism predicted adrenocorticotropin hormone responsivity to corticotropin release hormone challenge following dexamethasone suppression in the depressed subjects. Unfortunately control subjects were not separated by the FKBP5 genotype so it is difficult to say whether or not this polymorphism reflects cortisol regulation in the general population. The 5-HTT polymorphism results suggest that trait 5-HT mediates the effect of psychosocial stress on depression, while the FKBP5 data suggest that trait glucocorticoid responsivity predicts response to serotonergic and noradrenergic medications. Both studies suggest a reciprocal gene-by-environment interaction between stress and monoamines, where the environmental manipulation of one system interacts with the genetic contribution by the other in the manifestation of depressive symptoms. These data provide genetic evidence for the convergence of the monoamine and stress hypotheses of depression.

Evidence suggesting that both psychosocial stress and monoamines affect the hippocampus in animal models of stress and depression and in brains from depressed individuals highlights the above human genetic observations. Genetic and pharmacological manipulation studies suggest that monoamines modulate the effects of stress on the hippocampus and vice versa. The effects of stress on the hippocampus are pharmacologically and genetically reversible. Fluoxetine reverses both the behavioral sequelae and the decrease in cellular proliferation resulting from inescapable shock [25]. Similarly, the monoamine oxidase inhibitor moclobemide reverses the decrease in proliferation resulting from chronic stress [26]. Stress-induced decrease in hippocampal volume reverses with the serotonin reuptake enhancer tianeptine [27]. This drug also reverses stress-induced decreases in cellular proliferation, dendritic arborization, and release of brain-derived neurotrophic factor (BDNF) [27, 28]. Similar hippocampal responses to 5-HT reuptake enhancement or inhibition appear paradoxical. Explanations for these observations include an intriguing possibility that chronic enhancement or inhibition of the 5-HTT may result in similar molecular and ultimately structural and physiological adaptations by the cells. Another possibility that has some experimental support [28a] is that tianeptine exerts its effects on the hippocampus through a non-serotonergic mechanism. In one study, tianeptine was effective in preventing stress-induced decrease in dendritic arborization in CA3, while the SRIs fluoxetine and fluvoxamine were not [28]. This is the only evidence suggesting that stress-induced decrease in cellular

proliferation and dendritic arborization is pharmacologically dissociable. The connection, or lack thereof, between stress-induced decreases in neurogenesis and dendritic arborization in the CA3 remains to be adequately explored.

Human studies on the effect of antidepressant treatment on the hippocampus parallel the results of the animal findings [29]. Patients who suffer from posttraumatic stress disorder (PTSD) demonstrate increased performance on verbal declarative memory tasks and increased hippocampal volume following treatment with the SRI paroxetine. Consistently, gene expression studies in animals suggest the hippocampus as a site of convergence between stress and monoamines. One report indicates that stress-induced changes in hippocampal expression of genes related to proliferation and plasticity were reversed by treatment with the tricyclic antidepressant clomipramine in tree shrews [30]. Of course, 5-HT and NE receptors are expressed throughout the brain, and precise anatomical targets for the clinical effects of antidepressants have not been elucidated. Nevertheless, taken together these findings strongly support a role for 5-HT in modulating stress-induced changes within the hippocampus. Accordingly, investigation into biological mechanisms by which monoamines and stress modulate hippocampal plasticity became of paramount importance in understanding the biological mechanisms of antidepressant action.

20.4 HIPPOCAMPAL NEUROGENESIS AND DEPRESSION

Brain plasticity was traditionally accepted to result from chemical and possibly structural changes in existing neurons. The possibility that neuronal cells are continually added to the adult brain was intensely rejected by the scientific community until very recently [31]. However, the advent of newer techniques to detect DNA replication and thus cell division have led to the acceptance that new neurons are generated in the adult brains of rodents and other mammals. In a seminal study, Erickson and colleagues demonstrated that neurogenesis occurs in adult humans by identifying new neurons, which incorporated the thymidine analog bromodeoxyuridine (BrdU), in the hippocampi of deceased cancer patients who received BrdU as a diagnostic agent [32]. With the eventual acceptance that adult neurogenesis was pertinent to human neurobiology, great interest developed in directing neurogenesis to combat neurodegenerative disease. Sophisticated cell culture models focused on identifying neuronal progenitor cells and elucidating mechanisms of division and differentiation of these progenitors into functioning neurons. To date, there have been no large clinical implantation trials for neuronal progenitors. Moreover, clinical attempts to implant fetal dopamine-producing cells into the substantia nigra to combat Parkinson's disease have not met with success [33]. Limited success in employing neurogenesis for the treatment of neurodegenerative illness necessitated a closer analysis of the normal function of neuronal turnover in the adult brain. Some clues to the normal function of neurogenesis came from an observation that, although robust, adult neurogenesis is exclusively restricted to the layer of granule cells lining the ventricular system (SVZ) and subgranular zone of the dentate gyrus in the hippocampus (SGZ) in rodents (see Chapter 7 in Volume 3 of this handbook). In humans, adult neurogenesis has been conclusively demonstrated only in the SGZ [32].

The normal function of adult neurogenesis, if there is one, must reflect the normal function of the two brain structures to which it is restricted. The hippocampus has

been firmly established in playing a critical role in learning and memory and a role in the brain's response to psychosocial stress, as described above. The possibility that adult neurogenesis contributes to hippocampus-dependent learning and memory is currently under intense investigation [34]. Observations that the hippocampus may play a role in affective and anxiety disorders have stimulated investigations of hippocampal role in rodent models of anxiety and depression. Several lines of evidence suggest that hippocampal neurogenesis is relevant to the pathophysiology of affective and anxiety disorders. Exposure to mental stress reproducibly decreases neurogenesis in rodent models. Social subordination decreases proliferation of adult hippocampal progenitors in marmosets [35], tree shrews [27, 36, 37], and rats [38]. Immobilization [39], physical restraint [40], and foot shock [25, 39] all decrease incorporation of BrdU into dividing hippocampal progenitors in rats, as does chronic mild stress in mice [41]. Treatment with antidepressants—including SRIs, NRIs, monoamine oxidase inhibitors, and electroconvulsive therapy—increases neurogenesis in the hippocampus (reviewed in [42]). Provocatively, antidepressant treatment reverses the effects of chronic unpredictable stress in mice [41] and of inescapable shock in rats [25] on hippocampal neurogenesis. The reversal of stress-induced decrease in hippocampal neurogenesis by antidepressants is reminiscent of the reviewed effect of stress and antidepressant treatment on hippocampal volume and dendritic morphology. Nevertheless, the mechanism by which chronic stress modulates hippocampal neurogenesis in the dentate gyrus and dendritic arborization in CA3 and whether these two events are related remain unsolved beyond an established role for the hypothalamic–pituitary–adrenal (HPA) system in both. Efforts at elucidating the mechanisms by which stress modulates hippocampal changes are ongoing.

Still more intriguing is the role of these two hippocampal adaptations in the behavioral response to chronic treatment with antidepressants. In a provocative study Santarelli and colleagues demonstrated that neurogenesis was necessary for antidepressants to induce behavioral changes [43]. The investigators ablated hippocampal neurogenesis in mice by specifically exposing hippocampi to X-ray irradiation, which interferes with DNA synthesis and results in death of dividing cells. There was no evidence of death of mature hippocampal neurons and SVZ neurogenesis was spared. Control mice show more exploratory behavior in the novelty-suppressed feeding or improved coat state in the chronic unpredictable stress tests in response to chronic treatment with fluoxetine or imipramine. Following ablation of hippocampal neurogenesis, mice failed to show the same responses to antidepressant treatment. A similar effect was not seen when the SVZ neurogenesis was ablated and in sham-irradiated animals. These data are first to bring forth a possibility of a causal relationship between increased neurogenesis and antidepressant action.

20.5 STAGES OF ADULT NEUROGENESIS

Understanding the diverse stages of hippocampal progenitor maturation is necessary to examine the putative cellular targets of antidepressant medications. Within the hippocampus, neurogenesis is restricted to the subgranular zone of the dentate gyrus (Fig. 20.3). (See also Chapter 7 in Volume III of this handbook.) There, radial glia which express markers of differentiated and activated astrocytes undergo asymmetric division into two daughter cells. The daughter that does not inherit the prolonged

Figure 20.3 Neurogenesis in the adult mouse hippocampus. The hippocampal formation extends longitudinally along a dorsoventral axis in the rodent brain. A transverse section reveals the characteristic trisynaptic circuit that is enlarged in a separate panel. The perforant path (PP) comes from the entorhinal cortex (EC) and innervates the dendrites of granule cells in the molecular layer (Mol) of the dentate gyrus (DG). Granule cells send axons to CA3 pyramidal neurons that constitute the mossy fibers (mf). Schaffer collaterals (sc) are the projections of CA3 pyramidal neurons toward CA1 pyramidal neurons, which in turn project to the subiculum (S). The dentate gyrus is composed of the molecular layer containing the dendrites of the granule cells, the granule cell layer (GCL) containing the cell bodies of the granule cells, and the subgranular zone (SGZ) containing the proliferating progenitor cells. As these progenitors differentiate into mature granule cells, they migrate within the inner third of the GCL and extend progressively longer and more complex dendrites in the molecular layer. [From F. Doetsch and R. Hen, *Curr. Opin. Neurobiol.* 15(1), 121–128. Reprinted with permission from Elsevier.] (See color insert.)

morphology of the radial glia undergoes symmetric divisions in a subgranular pool of cells referred to as the rapidly proliferative pool. At each division, the cell from the proliferative pool undergoes a fate decision of either dividing or migrating into the dentate to differentiate into a granule or a glial cell. Interestingly, the fate-determining decision is dependent on excitatory neuronal activity [44] and is thus regulated by neuronal inputs into the dentate.

Upon migrating into the granule layer, the “immature” neurons express markers that are not expressed by mature granule cells. Specific proteins with established roles

in neuronal migration have a tightly controlled window of expression during granule cell maturation in both developmental and adulthood neurogenesis [45–48]. Immature cells form axonal and dendritic processes within 10 days of division [49]. They then go on to develop functional connections with outputs to the CA3 target pyramidal cells [50]. Full characterization of functional connectivity of the new neurons remains to be carried out. Interestingly, the immature neurons have unique physiological properties and do not share excitation parameters with their mature counterparts [51, 52]. Specifically, CRMP 4/doublecortin positive immature neurons express low-threshold calcium channels and are more susceptible to electrical excitation [46]. Consistently, investigators have found that long-term potentiation (LTP) is easier to elicit in young neurons (four to eight weeks old) compared to old ones [46]. The unusual physiological properties of immature neurons, including a possible excitatory role for γ -aminobutyric acid (GABA) [53], are reminiscent of the excitation parameters exhibited by the immature neurons in the developing brain. Since adult hippocampal neurogenesis is persistent, identification of distinct physiological properties in synaptically connected immature neurons enticed speculation that the combined pool of immature cells may have a unique role in hippocampal information processing and ultimately behavior [34]. In fact, several attempts to identify physiological activity attributable to immature cells led to the identification of a distinct form of LTP in the dentate gyrus which is elicited by weak stimulation of the medial perforant path [46]. Ablation of the subgranular zone neuronal precursors by gamma [46] and X-ray [54] irradiation obliterated this form of LTP three weeks later. Thus, immature dentate neurons express distinct proteins, are more susceptible to plasticity, and constitute a cellular pool with conduction properties that are measurable at a circuit level.

Finally, while it is clear from BrdU pulse-labeling studies that cells that survive for the first month following DNA replication are likely to survive for at least six months to one year [55], it is also clear that many cells undergo apoptosis and die at some point prior to one month. The net cellular turnover in the adult dentate gyrus is difficult to accurately assess using BrdU incorporation, given the dilution of the nucleotide in a rapidly dividing cellular pool. The possibility that older neurons in the dentate gyrus die to make room for newer ones and that this process may facilitate the encoding of experience is especially intriguing and needs to be experimentally assessed. Thus, what is broadly termed *adult hippocampal neurogenesis* involves steps of asymmetric division of glia, rapid division of neuronal progenitors, fate selection, differentiation and migration, maturation, and cellular survival as an overarching theme. Antidepressants and stress may exert their behavioral effects at any of these steps by increasing neurogenesis, influencing the function of young neurons, or directing the integration of new neurons into select circuits.

20.6 NEUROGENESIS REGULATION BY STRESS HORMONES

The effect of psychosocial stress on adult neurogenesis has already been discussed, as was the role of adrenal hormones in mediating stress-induced hippocampal changes. The possibility that the new cells may directly incur the toxic effect of stress on the hippocampus has been investigated in several animal models. Both glucocorticoids and mineralocorticoids have almost immediate transient surges following stress exposure. Early studies demonstrated a sustained increase in cells

undergoing DNA replication in adrenalectomized rats [56]. Later studies conclusively demonstrated that acute and chronic administration of corticosterone decreased proliferation of neuronal progenitors [57, 58]. Administration of a synthetic GR agonist similarly decreased proliferation of hippocampal cells fated to become neurons [59].

While removing glucocorticoid stimulation increases cell proliferation, it is also reproducibly associated with death of mature neurons in the dentate [60] as well as other hippocampal regions [61–63]. Adrenalectomy-associated hippocampal cell death is preceded by GR down regulation and can be reversed by administration of exogenous glucocorticoids [64]. While the neurotoxic effects of adrenalectomy were reversed by glucocorticoid treatment, the proliferative effect was not [57]. Nevertheless, taken together with the observation that GRs and MRs are present on neurons throughout the hippocampus [20], the data suggest that neurogenesis and the survival of mature hippocampal neurons are under adrenal hormone regulation. Moreover, the two effects of adrenal hormones—progenitor proliferation and mature cell survival—appear to be dissociable.

In order to shed light on the mechanisms by which stress regulates neurogenesis, Garcia and colleagues surveyed the expression of GRs and MRs on dentate granule cells at different stages of maturation in adult mice [65]. The investigation revealed that GR is expressed differentially on radial glia and rapidly proliferative cells but not at all on immature neurons. As described by others, GR was expressed on all mature neurons. MR was present only on mature cells, and the proportion of the cells in each pool that expressed MRs differed with the age of the animals. These results suggest that stress can differentially regulate neurogenesis via glucocorticoids directly during the early stages of maturation, while both glucocorticoids and mineralocorticoids can directly impact mature neurons. The role of adrenal hormones in the survival of maturing neurons, if there is one, is likely to be indirect given the absence of GRs or MRs on immature neurons. Thus, differences in GRs and MRs on cells at various points of maturation suggest that psychosocial stress could regulate hippocampal function by selective and different effects on neurons at different stages of maturation.

Stress during certain periods can have lasting effect on neurogenesis and on the response of neurogenesis to stimulation by glucocorticoids. Early, prolonged maternal separation has long-lasting effects of decreasing hippocampal neurogenesis in rats [66]. This effect was reversible by lowering corticosterone levels in the maternally deprived animals when they were adults by adrenalectomy with low-dose corticosterone replacement. A similar reduction of corticosterone did not affect neurogenesis in animals that were not maternally deprived. Interestingly, the HPA axis of the separated animals responded appropriately to stressful stimuli when they were adults, but the effect of early stress on neurogenesis was sustained at all time points tested. Specifically, there was a decrease in cell proliferation and immature neurons but no significant changes in the number of mature neurons. The maternally deprived animals also failed to suppress neurogenesis in response to acute stressful stimuli later in life, notwithstanding their normal HPA response. The baseline corticosterone levels did not differ between deprived and control animals. Together these data suggest that early life stress has long-lasting effects on how hippocampal progenitors respond to glucocorticoids and are reminiscent of the human literature on early life stress conferring lasting risk for depression.

20.7 NEUROGENESIS REGULATION BY SEROTONIN AND NOREPINEPHRINE

Observations that hippocampal neurogenesis was increased in animals treated with antidepressants and that stress-induced decrease in neurogenesis could be reversed by antidepressant treatment sparked much speculation that neurogenesis is regulated by monoamines. Early studies showed that chemical denervation of serotonin fibers by injection of toxins into the dorsal and medial raphe, where all of the serotonin-producing cell bodies reside, reduced hippocampal and subventricular neurogenesis [67]. Full depletion of serotonergic innervation over a one-month period reduced cell proliferation by 60%, and reinnervation of the DG either after prolonged recuperation [68] or following direct implantation of raphe neurons into the DG [69] increased proliferation in the same model. Interestingly, implantation of nonserotonergic embryonic brain tissue into the DG did not have the same effect on cell proliferation, suggesting that serotonin was an important regulatory element. In the same set of studies, investigators also noted that PSA-NCAM (a marker of immature neurons) was affected in a manner consistent with the observed changes in proliferation. Unfortunately, the time course of analysis did not allow the investigators to answer the question of whether immature cells were affected as a consequence of modulating progenitor proliferation or if serotonin affected the immature cells themselves. These studies demonstrated that 5-HT plays a role in progenitor cell proliferation in the DG; attention was subsequently focused on the mechanisms by which serotonin achieves this effect.

Efforts to discern which serotonin receptors could modulate the 5-HT effect on neurogenesis produced several results. Early reports of a possible role for 5-HT_{1A} in cell division in tissue culture models actually precede the papers firmly establishing the presence of neurogenesis in the mammalian brain [70]. Akbari and colleagues noted that the fetal microcephaly induced by treating pregnant rats with cocaine was reversed if the neonates were treated with 5-HT_{1A} agonists [71]. The investigators then argued that the receptor was required for developmental neurogenesis. Further investigation of the role of 5-HT_{1A} in neurogenesis demonstrated that exposure to antagonists of the postsynaptic receptor resulted in decrease in adult hippocampal neurogenesis [72], while treatment with a 5HT_{1A} agonist had the opposite effect [43]. Taken together, the tissue culture studies and the rodent pharmacological manipulations are consistent with each other and point to a positive regulatory role for the 5-HT_{1A} receptors in neurogenesis.

A more recent pharmacological analysis investigated the ability of several 5-HT receptors to regulate neurogenesis [73]. Inhibitory 5-HT_{1A/1B} and stimulatory 5-HT_{2A/2C} receptors have been implicated in depression and anxiety and were examined in the study. The investigators confirmed the earlier observations that activating the 5-HT_{1A} receptors increases proliferation in both the SGZ and the SVZ. Both direct induction of proliferation and rescue of proliferation after serotonergic depletion were assessed. The latter was used as a measure of postsynaptic heteroreceptor activity since depletion acts to mimic maximal effects of the inhibitory autoreceptors. The investigators performed a detailed analysis of proliferative changes in both the SGZ and the SVZ and found notable differences. First, stimulation of 5-HT_{1A} increased progenitor cell proliferation in both the SGZ and SVZ. However, rescue studies suggested that 5-HT_{1B} autoreceptors regulated

neurogenesis in the SVZ and 5-HT_{1B} heteroreceptors regulated neurogenesis in the SGZ. Moreover, stimulation of 5-HT_{1B} autoreceptors decreased SVZ neurogenesis while antagonism at the 5-HT_{1B} autoreceptors increased SVZ neurogenesis. The effect of 5-HT_{1B} on neurogenesis was thus very different from the effect of 5-HT_{1A}. The 5-HT_{1B} results may suggest that 5-HT_{1B} agonists are not ideal candidates for antidepressant development since efficacious antidepressants stimulate neurogenesis in the SGZ but not in the SVZ [43, 74].

Modulation of the 5-HT₂ receptors as targets for antidepressant treatment was discussed in the beginning of the chapter. Several antidepressants (mirtazapine, nefazadone, trazadone) have affinity for the 5-HT_{2A/2C} receptors. Furthermore, atypical antipsychotics which may have some antidepressant activity [75], [76] modulate 5-HT_{2A/2C} binding in the rat brain [77]. At least one of the atypical antipsychotics (olanzapine) was demonstrated to increase neurogenesis in the SGZ with chronic treatment [78]. Pharmacological manipulation of the 5-HT₂ receptors indicated that stimulating 5-HT_{2A} receptors inhibits neurogenesis in the SGZ while 5-HT_{2C} stimulation increases SVZ neurogenesis [73]. The investigators did not note an effect of 5-HT_{2C} in modulating SGZ neurogenesis. This does not appear consistent with the established antidepressant efficacy of 5-HT_{2C} antagonists. However, very recent work demonstrates that inhibition of the 5-HT_{2C} receptor with systemically administered antagonist selectively increases neurogenesis in the ventral hippocampus with the dorsal hippocampus unaffected [79]. Consistently, stimulation of 5-HT_{2C} is anxiogenic only when the agonist is injected in the ventral part of the hippocampus [80]. Indeed, numerous lines of evidence point to segregation of hippocampal function across the dorsoventral axis with the ventral part more important for affect regulation in rodents [81]. The dorsoventral hippocampal axis in rodents corresponds to the anterior–posterior hippocampal axis in humans (Fig. 20.2). Accordingly, the anterior–posterior human hippocampus is differentially affected by depression [82]. It would thus be interesting to reexamine the results from Banasr and colleagues for the possibility that the lack of 5-HT_{2C} effect in the whole SGZ was due to these receptors modulating neurogenesis only in the ventral hippocampus.

Lastly, while only chronic treatment with SRIs results in a proliferative increase, both chronic and acute treatments with the receptor-specific ligands have the same effect on neurogenesis. To this end, the mechanism by which 5-HT modulates neurogenesis is consistent with antidepressant developments discussed in the beginning of the chapter, where receptor sensitization was invoked to explain the delayed onset of SRI action and the mechanism of action of 5-HT_{1A/2A/2C} ligands. Serotonergic modulation of neurogenesis serves as an alternate hypothesis to receptor sensitization in the mechanism of the delayed action of serotonergic antidepressants. Some of the important studies needed to support this hypothesis are discussed at the end of this chapter.

In contrast to 5-HT, little is known about the mechanism by which NE regulates neurogenesis. NRIs are potent antidepressants, and noradrenergic fibers that radiate from the locus ceruleus project heavily to the DG. Like SRIs, chronic NRI treatment increases neurogenesis specifically in the SGZ, and experimental depletion of noradrenergic cells by chemical lesions results in a decrease in neurogenesis [83]. The 67% decrease in neurogenesis caused by depletion of NE in that study is strikingly similar to the 60% decrease from chemical lesions of the raphe cells [67].

Finally, while SRIs do not alter behavior and do not affect neurogenesis in mice devoid of the 5-HT_{1A} receptors, NRIs do both in 5-HT_{1A} knockout mice [43]. Thus, selective contribution of NE to regulation of neurogenesis in the SGZ is comparable to that of 5-HT and is likely to act via a different mechanism.

20.8 BEHAVIORAL READOUTS AND ANIMAL MODELS

The connection between antidepressant treatment and neurogenesis rests on correlative observations that compounds with antidepressant activity promote neurogenesis and at least one report that this increase is necessary for antidepressants to change rodent behavior [43]. Given the heterogeneity of depressive symptoms and the largely subjective nature of this disease, rodent models can only replicate certain aspects of MDD. The extensive body of literature discussing rodent models of depression is beyond the scope of this review and the reader is directed elsewhere [84, 85]. Nonetheless, it is important to note that the different behavioral tasks utilized in rodent studies model particular aspects of the disease. Conflict-based tasks such as the elevated plus maze, open field, and novelty-induced hypophagia bring into conflict the animal's innate drive to explore with anxiety-provoking stimuli and have greater face validity for anxiety disorders [86, 87]. However, these tasks respond to chronic but not acute antidepressant treatment in a way that is similar to MDD and anxiety disorders in humans [85, 87]. Conflict-based tasks may thus serve as better models for anxiety disorders or the highly prevalent comorbid depression with anxiety. The forced-swim and tail suspension tests seem to have adequate pharmacological predictive validity for known antidepressants without response to strictly anxiolytic benzodiazepines [85]. However, these tests respond to treatment acutely. Finally, learned helplessness has excellent face validity as a model for MDD but also responds to acute antidepressant treatment, thus falling short of recapitulating the delay in human response to pharmacological treatment. It is also important to mention that, consistent with the variability of human response to behavioral challenges, inbred rodent lines show great strain variability in all of the behavioral tests reviewed here [85]. The diversity of animal models for the complex disorder of brain function observed in MDD illustrates the importance of validating research findings by utilizing several models in any study and selecting an appropriate experimental strain.

20.9 CONCLUSIONS AND FUTURE DIRECTIONS

This chapter focuses on an apparent mechanism for convergence of the stress and monoamine hypotheses of depression. Major depressive disorder is widely thought to be linked to psychosocial stress, which often precedes its onset and its episodic exacerbations. Psychotherapeutic and psychosocial treatments for MDD focus on stress reduction, coping skills, and changing attitudes towards and perceptions of events that are experienced as stressful. The biological effects of stress on the human brain have been extensively studied and are most profound in the hippocampus. Serotonin and norepinephrine have also been implicated in the biology of MDD through pharmacological, genetic, and biological studies. Interestingly, studies of

risk-conferring genes, which are involved in 5-HT metabolism, suggest that the genetic risk burden of the 5-HT system is modified by stressful life events [21, 22]. Moreover, at least one study implicates a gene involved in the metabolism of glucocorticoids in genetic risk for MDD [23]. The risk-conferring allele in that study also predicts response to treatment with monoamine modulators. (Thus, the genetic burden of serotonin can be modified by stress, while the genetic burden of stress predicts response to modification of monoamine levels.) These data argue that the contributions of stress and monoamines to MDD are linked mechanistically.

Extensive evidence from animal models suggests that regulation of behavior by both monoamines and stress is associated with structural changes in the hippocampus. Consistently, human postmortem, structural, and functional imaging studies implicate the hippocampus in MDD. Within the hippocampus, we reviewed evidence suggesting that the volumetric changes seen in humans are consistent with decreased dendritic arborization in CA3 and CA1. Moreover, stress and monoamines regulate neurogenesis, and treatment with antidepressants protects the hippocampus from stress-induced decline in neurogenesis (Fig. 20.4). Here it is important to mention that given that neurogenesis is restricted to the SGZ of the dentate gyrus and the dentate constitutes a small portion of the hippocampus, it is unlikely that even a large reduction in neurogenesis could directly account for the observed declines in hippocampal volume. Given that dendrites account for a major component of hippocampal volume, decrease in dendritic arborization is more likely to account for volume reductions seen with stress and MDD. Nevertheless, regulation of hippocampal neurogenesis by stress and monoamines has been well documented, and elucidation of underlying mechanisms is ongoing. The specificity of antidepressant treatments for hippocampal but not subventricular neurogenesis is likewise intriguing. Studies exploring hippocampal response to stress and monoamine modulation implicate neurogenesis as a marker for both events. Taken together, these data suggest that stress and monoamines are involved in both the pathophysiology of depression and the regulation of adult hippocampal neurogenesis. Finally, at least one study demonstrates that hippocampal neurogenesis is necessary for behavioral responses to antidepressant treatment.

Several important experiments are needed to support the provocative observations that hippocampal neurogenesis is involved in the regulation of mood. First, while some of the molecular modulators of cellular proliferation have been identified, most of their cellular targets remain unknown. Future studies will need to address which stages of neurogenesis, if any, are directly impacted by glucocorticoids, monoamines, and other modulators. Most studies to date rely on markers of either cell division or immature neurons to assess the molecular mechanisms controlling neurogenesis. More definitive receptor profiling such as that carried out by Garcia and colleagues [65], combined with inducible genetic mouse models, can define cellular targets for the molecules that regulate neurogenesis. Identification of these cellular targets will be important for more refined therapeutic design if the role of neurogenesis in mood regulation proves to be mechanistic.

In order to more firmly establish the role of neurogenesis in MDD and antidepressant treatment, more corroborating evidence is needed. The requirement of hippocampal neurogenesis for the behavioral action of antidepressants will need to be validated using other behavioral tasks and other methods for ablating proliferation of progenitor cells. To this end a genetic system of ablating neurogenesis was

Figure 20.4 Hippocampal neurogenesis, stress, and antidepressant treatment. Schematic representation of a coronal section through a mouse brain. The expanded views in the panels above illustrate the dentate gyrus of the hippocampus with the cell bodies of young neurons in the subgranular layer and dendritic projections traversing the granule cell layer. Baseline neurogenesis is enhanced by antidepressants, reduced by stress, and the stress-induced reduction is reversed with antidepressant treatment. The expanded views in the bottom panels show a pyramidal neuron in CA3 with basal and apical dendrites extending outside the pyramidal cell layer (gray). Stress reduces the baseline arborization of apical dendrites. Tianeptine, but not serotonin reuptake inhibitors, reverses the effect of stress on dendritic arborization [87]. (See color insert.)

recently described [88]. This system is currently being used to repeat the behavioral and physiological results discussed in this chapter [54]. The use of sophisticated genetic manipulations could also allow for exploration of circuit properties of the new cells. While early studies demonstrated that new neurons make functional connections [46, 50, 54], there has been no report definitively characterizing extended circuitry of the new neurons. Delineation of the circuits employed by the new neurons should be useful in ascertaining how antidepressants change behavior at a circuit level.

While many elegant experimental approaches are adding to our insight to the function of neurogenesis in rodents, primate studies on the effect of depression and antidepressant treatment on neurogenesis continue to be lacking. Experimental studies in nonhuman primates should reflect the rodent findings if these data are relevant to human disease. Postmortem human studies are also necessary to help

determine whether stress and perhaps untreated depression decrease neurogenesis while antidepressant treatments increase neurogenesis. Human studies will also help to shed light on whether antidepressants increase hippocampal neurogenesis itself or alternatively prevent the stress-induced decrease in neurogenesis or both, as they do in rodents. Ultimately, naturalistic examples of ablating neurogenesis in humans, such as whole-brain irradiation for cancer treatment, may help to elucidate if neurogenesis is necessary for antidepressants to treat depression and anxiety.

Lastly, it is important to point out that other mechanisms underlying the pathophysiology of depression are likely to emerge. The medications reviewed in this chapter are efficacious for the treatment of depression and anxiety and act by inhibiting the reuptake of 5-HT and NE. These medications activate neurogenesis and are efficacious antidepressants. Yet, depression is a heterogeneous disorder which is likely to engage other brain regions [2, 89]. Consistent with this notion is the observation that there are patients resistant to treatment with SRIs and NRIs. Investigating the biological mechanisms underlying antidepressant treatments that do not alter neurogenesis should delineate other brain systems that are involved in MDD.

21.1 INTRODUCTION

Women have at least twice the risk of developing a major depressive episode compared with men. They are prone to develop depressive episodes during times of reproductive hormonal change during the menstrual cycle, pregnancy and the postpartum period, and the menopause transition. Studies in which only single samples of a specific hormone are measured generally have not been revealing with regard to the causes of this depressive diathesis. In contrast, studies in which investigators examine the abnormalities in the circadian rhythms of melatonin, cortisol, prolactin, and thyroid-stimulating hormone (TSH) during these reproductive epochs are more revealing about differences that distinguish depressed patients (DPs) from healthy normal control (NC) women. In this chapter, the authors focus on reviewing studies that measure the circadian profile of hormonal changes in relation to baseline changes in the reproductive hormones of estradiol, progesterone, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), comparing DPs with NCs during the menstrual cycle, pregnancy, postpartum, and menopause and across each of these reproductive epochs. Elevated prolactin levels characterize DPs at each reproductive epoch. Increased melatonin levels characterize menopausal and postpartum DPs, whereas decreased melatonin levels characterize premenstrual dysphoric disorder (PMDD) and DPs during pregnancy. Decreased cortisol levels distinguish menopausal DPs from healthy controls. Using circadian measures in well-defined diagnostic groups, further work is needed in order to identify common versus distinctive neuroendocrine profiles for DPs during each reproductive epoch. This information then could serve as a basis for developing more specific treatment modalities.

21.2 CIRCADIAN NEUROENDOCRINE STUDIES OF DEPRESSION DURING MENSTRUAL CYCLE

The depressive disorder linked to the menstrual cycle, PMDD, is defined in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) [1]. Studies in which the investigators examined the circadian rhythms of melatonin, cortisol, TSH, and prolactin in PMDD and NC women during the menstrual cycle are described below.

21.2.1 Melatonin

In healthy women, Nair et al. [2] found a phase delay of the nocturnal peak of melatonin secretion during the midmenstrual period (midcycle), although melatonin was sampled only every 2–4 h at two points in the cycle and without documentation

of estradiol or progesterone levels. Brzezinski et al. [3] and Berga and Yen [4] found that in NC women melatonin circadian rhythms are relatively stable and resistant to hormonal influences during the menstrual cycle. Shibui et al. [5] studied eight healthy women who underwent an ultrashort sleep–wake cycle schedule, a design that uses multiple nap tests to exclude masking effects and determine diurnal fluctuations of the circadian pacemaker. By this method they found that serum melatonin secretion was significantly decreased in the luteal compared with the follicular menstrual cycle phase.

In studies of women with depression, Parry et al. [6] observed that eight women with PMDD had an earlier (phase-advanced) offset of melatonin secretion, which contributed to a shorter secretion duration and a decreased area under the curve (AUC). Melatonin rhythms in eight NC women did not change significantly during four phases of the menstrual cycle in this study. In a larger follow-up study [7] of 21 PMDD and 11 NC subjects, in PMDD subjects, during the symptomatic luteal compared with the asymptomatic follicular menstrual cycle phase, melatonin onset time was delayed, duration was compressed, and AUC, amplitude, and mean levels were decreased. As in the initial study, in NC subjects, melatonin rhythms did not change significantly with the menstrual cycle.

21.2.2 Cortisol

Using the ultrashort sleep–wake cycle design in eight healthy women, Shibui et al. [5] observed that the amplitude of cortisol rhythms was significantly decreased in the luteal compared with the follicular menstrual cycle phase.

In a pilot study of eight women with prospectively documented PMDD who had multiple samplings for cortisol during midcycle (late follicular) and the late luteal menstrual cycle phase, Parry et al. [8] reported increased serum cortisol levels during the midcycle phase. In a study of 20 women with late luteal phase dysphoric disorder (LLPDD) [9] and 11 NC subjects in whom cortisol levels were measured every 30 min from hour 18:00 to 9:00, during the midfollicular (MF) and late luteal (LL) menstrual cycle phases, Parry et al. [10] found that in NC but not LLPDD subjects the cortisol peak was significantly delayed in the LL compared with the MF menstrual cycle phase. In a separate study of 15 women with PMDD and 15 NC subjects, Parry et al. [11] again observed altered timing but not quantitative measures of cortisol secretion in PMDD versus NCs: In the LL versus MF phase, the cortisol acrophase occurred 1 h earlier, on average, in NC but not in PMDD subjects.

21.2.3 Thyroid-Stimulating Hormone

In a study of eight healthy women undergoing ultrashort sleep–wake cycle schedules, Shibui et al. [5] found that the amplitude of the TSH rhythm was significantly decreased in the luteal compared with the follicular menstrual cycle phase.

In a study of the circadian rhythms of TSH in 23 PMDD and 18 NC subjects in which samples for TSH were measured every 30 min from hour 18:00 to 9:00 during MF and LL menstrual cycle phases, Parry et al. [12] observed that TSH rhythms occurred earlier in PMDD than in NC subjects.

21.2.4 Prolactin

In a study of 20 women with LLPDD and 11 NC subjects, Parry et al. [10] measured prolactin every 30 min from hour 18:00 to 9:00 during MF and LL menstrual cycle phases. In LLPDD patients, prolactin peak and amplitude were higher and acrophase earlier than in NC subjects. In a separate study of 23 PMDD and 18 NC subjects, Parry et al. [12] measured prolactin every 30 min from hour 18:00 to 9:00 during MF and LL menstrual cycle phases and found that PMDD patients had higher prolactin concentrations, consistent with previous findings.

21.3 CIRCADIAN NEUROENDOCRINE STUDIES OF DEPRESSION DURING PREGNANCY

Melatonin, cortisol, thyroid, prolactin, and reproductive hormones have been linked to mood changes occurring during pregnancy and postpartum (see reviews in [13–15]), but the circadian rhythms of these hormones have not been the focus of investigation. The studies in which investigators examined the circadian profile of these hormones are described below.

21.3.1 Melatonin

Pang et al. [16] examined plasma levels of immunoreactive melatonin, estradiol, progesterone, FSH, and β -human chorionic gonadotropin (β hCG) during pregnancy and shortly after parturition in 105 Chinese females. In pregnant females, there were significant negative correlations between melatonin and estradiol, melatonin and progesterone, β hCG and progesterone, and β hCG and estradiol and positive correlations between melatonin and FSH and progesterone and estradiol. The findings suggest that gonadal steroids inhibit and FSH potentiates circulating melatonin levels in gravid women and that circulating melatonin in the mother may affect in utero development and be the major source of blood melatonin in the fetus before parturition. Kivela [17] studied 12 women in early pregnancy and 11 women in late pregnancy and found that serum melatonin levels sampled every 4 h during the third trimester of pregnancy were significantly higher than those sampled during the first and the second trimesters and those of non pregnant control women. There was a positive correlation between the week of gestation and serum melatonin concentration at hour 11:00. The amplitude and duration of the nocturnal rise of melatonin were higher during late pregnancy, but there was no clear phase shift. Suzuki et al. [18] examined pregnant women and compared melatonin secretion rhythms sampled hourly from hour 18:00 to 8:00 in six good sleepers and six poor sleepers. Significant differences, using polynomial curve-fitting techniques, were found between the poor sleeper group (lower values) and the good sleeper group (higher values). Non significant trends were found for increased amplitude in the melatonin rhythm in poor sleepers. They also reported significant differences in the cortisol–melatonin ratio between poor sleepers (lower values) and good sleepers (higher values) during late pregnancy as assessed by subjective sleep logs [18]. The differences may reflect changes in the circadian pacemaker system of poor sleepers,

with increases in melatonin release being a response to counteract poor sleep. Nakamura et al. [19], sampling at hours 14:00 and 2:00 in 79 pregnant women (timing during pregnancy not specified), reported increases in maternal serum melatonin until the end of pregnancy which decreased to nonpregnant levels by the second day postpartum. Parry et al. extended initial observations [13] and studied eight women with a major depressive episode (MDE) during pregnancy and four NC subjects matched for age (within five years) and weeks pregnant (within four weeks) in which plasma melatonin was measured every 30 min from hour 18:00 to 11:00 in dim (<50 lux) and dark conditions. As in PMDD patients, DPs had earlier mean melatonin offset time ($p = 0.047$) and lower peak ($p = 0.019$) and AUC ($p = 0.007$) than NC subjects; onset times and durations did not differ ($p > 0.05$). In contrast, other investigators have observed increased melatonin levels or delayed offset in patients with an MDE, mostly in menopausal women [20–25].

21.3.2 Cortisol

Eriksson et al. [26] studied two women in early pregnancy (11–17 weeks), four in late pregnancy (34–38 weeks), and two nonpregnant control women and reported increased cortisol concentrations sampled at 30-min intervals (circadian time epoch not specified) in pregnant women with maintenance of the diurnal rhythm such that nadir levels occurred around midnight and marked elevations during the early morning hours. In the study by Suzuki et al. [18], nonsignificant trends were found for decreased amplitude in the cortisol rhythm. The decreased amplitude of the cortisol rhythm in poor sleepers was due to a suppression of the early morning rise (from 5:00 to 8:00). In an update of studies previously reported by Meliska et al. [27], the ratio of cortisol to melatonin in the morning from 4:00 to 11:00 was higher in DP than in NC subjects ($p = 0.005$).

21.3.3 Thyroid-Stimulating Hormone

Eriksson et al. [26] observed maintenance of a diurnal variation in TSH during pregnancy with maximal values around midnight as in nonpregnant women. An update of Parry et al. [13] found a nonsignificant trend toward lower mean TSH levels in eight pregnant DP as compared with four NC subjects.

21.3.4 Prolactin

Boyar et al. [28] found that in three pregnant women episodic prolactin secretion measured at 20-min intervals for 24 h at 12, 20, and 32 weeks gestation became augmented during nocturnal sleep, with increased mean prolactin levels achieved by increased secretion per secretory episode. Eriksson et al. [26] also reported episodic secretion of prolactin during pregnancy. In the study by Suzuki et al. [18], prolactin levels were high and showed no rhythmicity in both groups of pregnant good sleepers and poor sleepers. In an update of the study by Parry et al. [13], higher prolactin levels were found in eight DP compared with four NC subjects when weeks pregnant and body mass index (BMI) were applied as covariates in the analyses.

21.4 CIRCADIAN NEUROENDOCRINE STUDIES OF POSTPARTUM DEPRESSION

Postpartum depression is classified as an onset specifier for mood disorders in DSM-IV [1]. Studies in which investigators examined the circadian profile of melatonin, cortisol, TSH, and prolactin in relation to reproductive hormones are reviewed below.

21.4.1 Melatonin

Parry et al. [14] measured plasma melatonin every 30 min from hour 18:00 to 11:00 in dim (<50 lux) and dark light in 11 women with an MDE postpartum and 5 NC women approximately matched for age and postpartum month. DPs had a trend toward higher mean melatonin peak and AUC compared with NC subjects. When age, weeks postpartum, and BMI were applied as covariates in the analysis, melatonin offset was later in DPs than in NCs (hour 9:23 vs. 7:52, $p = 0.042$, one-tailed). Other timing measures (onset, duration) were not significantly different between groups.

Although not systematically studied in postpartum women, melatonin levels were reported lower in a majority of studies comparing DP with NC subjects [2, 29–37], and we found and replicated lower melatonin circadian rhythms in patients with PMDD and in combined pregnant and postpartum DPs compared with NCs [6, 7, 13, 38, 39].

21.4.2 Cortisol

Harris et al. [40] measured saliva twice daily for cortisol and progesterone from two weeks before delivery to day 35 postpartum in 120 primiparous women. Seven women developed major depression postpartum. Lower levels of evening cortisol, but not progesterone, in the immediate peripartum period were associated with postnatal depression. In a study of 11 postpartum DP and 5 NC subjects in which serum samples for cortisol were obtained every 30 min from hour 18:00 to 11:00, Parry et al. [41] observed no significant differences in cortisol between DP and NC subjects.

21.4.3 Thyroid-Stimulating Hormone

In a study of 11 postpartum DP and 5 NC subjects in which serum samples for TSH were obtained every 30 min from hour 18:00 to 11:00, Parry et al. [41] found a non significant trend toward lower TSH in DP compared with NC subjects.

21.4.4 Prolactin

In healthy postpartum women, in a rigorous endocrine study using frequent blood sampling, Liu and Park [42] examined prolactin concentrations obtained at 20-min intervals for 12–24 h in eight nonlactating postpartum women on a weekly basis between postpartum days 10 and 26. Serum prolactin levels remained elevated during this time with the diurnal pattern of secretion conserved. With each successive week

postpartum, serum prolactin concentrations declined. Asher et al. [43] examined plasma prolactin levels between hours 8:00 and 9:00 just prior to delivery and three days after delivery in 25 healthy postpartum women. The rise in prolactin plasma levels postpartum had a negative and significant correlation with scores on the Hamilton anxiety scale. The findings suggested that high prolactin plasma levels associated with milk production led to lower anxiety levels in lactating women.

In postpartum DPs, Harris et al. [44] observed that in 147 postpartum mothers, 14.9% of whom were depressed, plasma prolactin levels were inappropriately low in depressed women who breast fed. In other studies, however, hyperprolactinemia has been associated with depressive symptoms [45–47]. In a study of 11 postpartum DP and 5 NC subjects in which serum samples for prolactin were obtained every 30 min from hour 18:00 to 11:00, based on updated data from Parry et al. [41] from breastfeeding mothers, prolactin from hour 4:00 to 11:00 was elevated in DPs relative to NCs [mean (\pm standard error, SE) = 80.1 (\pm 5.2) versus 38.8 (\pm 6.0) ng/mL, p = 0.006] when weeks postpartum and BMI were applied as covariates in the analyses. In contrast, Abou-Saleh et al. [48], in a study in which only a single morning sample was obtained, found significantly lower plasma prolactin levels in women with postpartum depression.

21.4.5 Estradiol

In an update of Parry et al. [41], estradiol was lower in DPs than in NCs (p = 0.035) when age, weeks postpartum, BMI, and breastfeeding status were applied as covariates in the analyses.

21.5 CIRCADIAN NEUROENDOCRINE STUDIES OF MENOPAUSE

21.5.1 Melatonin

In healthy menopausal women, Okatani et al. [49] studied nocturnal serum melatonin concentrations every 2 h in 44 postmenopausal women. They found a steep, age-related decline in nocturnal melatonin secretion lasting up to 15 years postmenopause, with a gradual decline thereafter. Daily oral administration of conjugated estrogen (0.625 mg) suppressed nocturnal melatonin secretion. Based on comparisons with premenopausal women, the authors suggested that transient elevated nocturnal melatonin secretion during menopause might be related to a low-estrogen environment.

In depressed menopausal women, Blaicher et al. [21] evaluated overnight urinary excretion of 6-sulfatoxymelatonin (6-SMT) using a radioimmunoassay in 60 postmenopausal women. Compared with healthy controls, 6-SMT values were significantly higher in depressed females. Patients with hyperprolactinemia showed a trend toward an elevated average nocturnal melatonin concentration. Melatonin levels were significantly lower in patients with insomnia and obesity. In a study of 382 postmenopausal women Tuunainen et al. [23] found that women with major depression compared with NC women without mood disorder, had significantly delayed urinary 6-SMT offset with a trend for increased excretion, particularly in those women with a lifetime history of mood disorders. Kripke et al. [24] found, in 72

volunteers aged 60–78 years, that a lifetime history of any affective disorder was significantly associated with greater urinary 6-SMT excretion in home and laboratory conditions. In an update of a report on the effects of hormone replacement therapy (HRT) in menopausal DPs versus NCs, Parry et al. [25] measured plasma melatonin every 30 min from hour 18:00 to 10:00 in dim (<30 lux) and dark conditions and found, by multivariate analysis, that mean plasma melatonin across all time intervals was higher in 16 DPs than in 9 NCs ($p=0.033$). DPs did not differ significantly from NC subjects on melatonin variables of onset, offset, duration, AUC, or peak at baseline or after 17- β estradiol (E2) treatment.

21.5.2 Cortisol

In a study of 42 healthy menopausal women (mean age 69.6 years), of whom 20 were on estrogen replacement therapy (ERT), Prinz et al. [50] found that elevated 24-h urinary free cortisol was associated with impaired sleep and earlier awakening in older women not on ERT but not in women on ERT.

Antonićević et al. [51] reported that nocturnal cortisol secretion in depressed menopausal women sampled every 30 min between the hours 20:00 and 22:00 and every 20 min between the hours 22:00 and 07:00 was increased in nine postmenopausal patients with depression, while a decrease was noted in nine postmenopausal controls. Parry et al. [25] studied menopausal DPs versus NCs after HRT. DPs had lower serum cortisol levels across time than NCs (hours 18:00 to 10:00, $p=0.012$). Estradiol (oral E2, 1–2 mg) or other treatments [progesterone (P4): medroxyprogesterone acetate, 2.5–5.0 mg in NCs; antidepressant (AD): fluoxetine, 10–40 mg in DP] did not significantly alter mean total cortisol levels in either group. After estrogen treatment, cortisol amplitude ($p=0.016$) and mesor ($p=0.028$) were lower in DPs than in NCs. After estrogen plus progesterone treatment in NC subjects, cortisol peak time occurred earlier compared with baseline ($p=0.036$).

21.5.3 Thyroid-Stimulating Hormone

Ballinger et al. [52] reported that clinically depressed late premenopausal women had significantly higher levels of TSH. In a study of the effects of HRT in menopausal DPs versus NCs by Parry et al. [25], mean TSH levels did not differ between NCs and DPs at baseline. After E2, but not other treatments, TSH values increased relative to baseline in NCs but not in DPs. For TSH nadir, there was a significant treatment–diagnosis interaction. TSH nadir and mesor increased with E2 treatment in NCs but not in DPs.

21.5.4 Prolactin

In healthy menopausal women, Schiff et al. [53] studied the effects of conjugated estrogens (0.625 mg) and placebo in 10 postmenopausal women during sleep and found that estrogen compared with placebo administration blunted LH and prolactin changes but not the rise in cortisol. Fernandez et al. [54] found that morning levels of serum prolactin were lower during menopause compared with pre- or perimenopause. In a study of the effects of HRT in menopausal DPs versus NCs by Parry et al. [25], mean prolactin levels did not differ in NCs and DPs at baseline.

When serum P4 level was included as a covariate in the analysis, adjusted mean prolactin was lower in DPs, overall, than in NCs ($p = 0.020$). E2 treatment produced a treatment–time–diagnosis interaction ($p = 0.014$): DPs, but not NC subjects, had elevated mean prolactin levels from hour 18:00 to 23:00 ($p = 0.001$) and from hour 5:00 to 10:00 ($p = 0.005$) but not from hour 23:30 to 4:30 ($p > 0.05$). Prolactin amplitude increased after E2 treatment in both NCs and DPs ($p = 0.046$) and prolactin mesor was higher in DPs than in NCs ($p = 0.018$).

21.5.5 Follicle-Stimulating Hormone

In an update of Parry et al. [25], FSH was higher in DPs than in NCs ($p = 0.045$) when age and BMI were applied as covariates in the analyses.

21.6 COMPARISONS OF CIRCADIAN NEUROENDOCRINE HORMONES ACROSS REPRODUCTIVE EVENTS

21.6.1 Menstrual Cycle

Studies of circadian hormonal profiles (melatonin, cortisol, TSH, prolactin) in DPs versus NCs during the menstrual cycle did not differ significantly from other women during pregnancy, postpartum, or menopause.

21.6.2 Pregnancy

In pregnant women, mean plasma melatonin was higher compared with women studied during the menstrual cycle ($p = 0.001$), postpartum ($p = 0.001$), or menopause ($p = 0.002$). In DP compared with NC women, however, the mean plasma melatonin level was lower in pregnant DPs than in NCs from hour 4:00 to 11:00 ($p = 0.003$; see Fig. 21.1). Mean serum cortisol was elevated in both NC and DP pregnant subjects, relative to the other groups ($p = 0.001$). Pregnant DPs (but not NCs) had elevated mean LH levels relative to PMDD, postpartum, and menopausal DP (all p values less than zero).

21.6.3 Postpartum

In NCs and DPs, MLT offset was earlier ($p = 0.001$) and AUC was smaller ($p = 0.001$) in postpartum than in menstrual subjects when age, weeks postpartum, BMI, and breastfeeding status were applied as covariates in the analyses.

21.6.4 Menopause

In both NC and DP menopausal women, mean total serum TSH from hour 18:00 to 11:00 was elevated relative to menstruating ($p = 0.015$), pregnant ($p = 0.025$), and postpartum ($p = 0.016$) women. When age and BMI were applied as covariates, FSH was higher in menopausal than in pregnant ($p = 0.001$), postpartum ($p = 0.001$) and menstruating women ($p = 0.001$).

Figure 21.1 Mean morning plasma melatonin levels in NCs vs. DPs. Numerals in parentheses indicate *N* per group. Asterisks denote significant differences between DPs and the corresponding NC group: (**) $p < 0.01$.

21.7 SUMMARY

For menstrual cycle studies of serum or plasma melatonin, the more rigorous studies that sampled more frequently, at 30-min intervals, to obtain more precise timing measures, suggest that in NC subjects melatonin circadian rhythms are relatively stable and resistant to hormonal influences during the menstrual cycle. In contrast, women with well-defined mood symptoms during the menstrual cycle have decreased amplitude (quantitative) measures of melatonin which are associated with changes in phase markers in the symptomatic luteal phase. The findings suggest that depressed patients have a decreased amplitude of the circadian pacemaker that impairs their ability to regulate biological rhythms.

With regard to the limited number of studies of cortisol and TSH circadian rhythms during the menstrual cycle in healthy versus depressed women, the available data suggest more group differences in the timing rather than in the quantitative measures of cortisol secretion. In contrast to cortisol and TSH, increased prolactin amplitude measures differentiate DPs versus NCs during the menstrual cycle, although the findings are based on only two studies.

During pregnancy, some of the inconsistencies in the studies of melatonin circadian rhythms may be attributed to different sampling frequencies and assay and analytic methods and variations in the influence of sleep patterns and gonadal steroid levels. In toto, amplitude measures of melatonin tend to increase in the later stages of pregnancy and are more marked than phase changes. Although the studies that examine the circadian rhythms of cortisol, TSH, and prolactin during pregnancy are few in number with small sample sizes and interpretations are limited by the different methodologies employed, the majority of studies suggest that diurnal rhythms are maintained during pregnancy, with more changes observed in amplitude than in phase. Prolactin levels are higher in depressed compared with healthy pregnant women, as they are in other reproductively related depressive disorders, when covariates of weeks pregnant and BMI are controlled for in the analysis.

Postpartum studies of melatonin, cortisol, TSH, and prolactin circadian rhythms also are limited by small sample sizes and lack of frequent hormonal sampling to

assess circadian rhythmicity. Based on the limited available data, melatonin and prolactin tend to be increased in postpartum depressed patients compared with healthy women. In contrast, in healthy postpartum women, higher prolactin levels are associated with decreased anxiety in lactating women. Estradiol levels are lower in DP compared with NC postpartum women, again when age, weeks postpartum, BMI, and breastfeeding status are applied as covariates in the analyses.

In studies of menopausal women, based on the limited data available from plasma and urinary samples of melatonin, menopausal DPs, compared with NCs, tend to have higher melatonin amplitude measures. In contrast, cortisol circadian rhythms are lower in menopausal DPs compared with NCs. TSH and prolactin circadian rhythms do not differ between depressed and healthy menopausal women. Estrogen treatment, however, has differential effects on cortisol, TSH, and prolactin measures in the two groups. FSH levels are higher in DP than in NC menopausal women when age and BMI are applied as covariates in the analyses.

Across reproductive epochs, it is noteworthy that the mean of melatonin and cortisol circadian rhythms is higher in pregnant compared with menstruating, postpartum, or menopausal women, although in depressed pregnant women the levels of melatonin in the morning are lower than in healthy pregnant women. Evening TSH levels are higher in menopausal DPs and NCs compared with other groups.

21.8 CONCLUSIONS

Certain circadian neuroendocrine features distinguish depressed patients from healthy controls across reproductive epochs: Elevated prolactin levels characterize menstruating, pregnant, postpartum, and menopausal depressed groups compared with healthy control women. Cortisol levels are lower in depressed menopausal women compared with healthy groups as they are in patients with atypical depression [55–58]. Melatonin levels are lower in menstruating and pregnant depressed women and higher in postpartum and menopausal depressed women compared with healthy women. More focus on the pathological timing of circadian rhythms in future studies might serve to clarify these neuroendocrine abnormalities. To make more valid comparisons, these variables will need to be examined for the influence of modulating factors such as age, season of the year studied, BMI, menstrual cycle phase, week pregnant or postpartum, menopausal year, and estradiol and progesterone levels in well-defined diagnostic groups. With more precise measurements and larger sample sizes, further work in each of these reproductively related depressive disorders would serve as the basis of developing treatment modalities targeted to each specific population. These endeavors also have the potential to yield valuable information on how changes in reproductive endocrine function affect the brain's regulation of circadian rhythms and mood.

An ideal chapter on the neurobiology of bipolar disorder (BPD) and its pharmacotherapy would include a review of an integrated understanding of BPD at the molecular, biochemical, neurophysiological, and neuroanatomical levels, with a rational discussion of the site of the therapeutic effects resulting from drug intervention. While this level of knowledge remains to be fully elucidated for most of the known diseases in humans, given the particular complexity of the interaction of the physiological, genetic, and environmental factors within the brain governing the expression of BPD, such understanding at this time appears beyond the horizon. For the purpose of this chapter we will describe some of the most compelling on-going research in this field forming the basis of existing theories of BPD neurobiology and mechanisms of action of antibipolar drugs. At the outset we caution against premature closure, since we do not currently know the most relevant pieces of the puzzle and the most heuristic avenues for investigation may have yet to be identified.

22.1 GENETICS

One well-established fact is the existence of genetic influences on the etiology of BPD, as evidenced in twin and adoption studies. The family pattern is not Mendelian in nature with statistical evidence ruling out a single major gene; rather, BPD is likely inherited through a complex interaction of widely shared genes with low levels of expression, similar to diseases such as diabetes and primary hypertension. Unlike the situation in Alzheimer's and Parkinson's diseases, no pedigree has been discovered where a single gene is operating. Even one such pedigree would jumpstart our studies of the biochemical and molecular pathways involved, as with the discovery of amyloid precursor [1] protein mutations and Parkin [2] mutations.

Linkages between BPD and several large chromosomal regions have been reported in more than one study, although none have been replicated in every study [3]. Moreover, many linkages have been reported and it is likely that some of the findings may remain relevant for selected population genetic isolates and others observed by chance. The chromosomal regions are very broad, and no one gene is clearly implicated. Some of these linkages may reflect nonspecific modifier genes, such as a gene for decreased pelvic diameter that could contribute to increased perinatal hypoxia. Perhaps some of the most promising avenues in this field involve the identification of genes that affect response to mood stimulants and circadian rhythms in both humans and animals [4]. Since such genes have a behavioral phenotype, the pathways around them could contain genes that are etiological and may serve as relevant targets for BPD pharmacotherapy.

22.2 POSTMORTEM BRAIN NEUROANATOMICAL FINDINGS

The absence of postmortem pathology once distinguished psychiatric illness from neurological illness. This concept is no longer heuristic. Harrison and Weinberger [5] recently summarized the neuropathology of schizophrenia by saying that the null hypothesis can be rejected, but a replicable specific defect cannot yet be described. BPD postmortem neuropathology could be similarly described.

Recent studies of postmortem brain tissue find prefrontal cortical and limbic microstructural alterations in patients with bipolar illness compared with controls [6]. Gross neuroanatomical examination of postmortem brain from BPD patients does not reveal any visible changes. The widening of cortical sulci and narrowing of gyri reported by some neuroimaging studies in mood disorder patients are observed in very few postmortem specimens from similar populations. Qualitative microscopic examination of postmortem brain from BPD patients does not reveal any visible neuropathological changes such as focal lesions or the plaques and tangles seen in Alzheimer's disease. However, in some cases, microvascular changes in the gray and white matter are noticeable, although this could be due to repeated stress or drug treatment.

Recent application of nonbiased quantitative stereological cytoarchitectonic cell counting and detailed morphometric methods employed on postmortem tissues from patients with mood disorders provide evidence that mood disorders are characterized by specific changes in the number, density, or size of both neurons and glial cells. Although there are quite a few reports, each based on rather small sample sizes, three

groups have published such studies using well-characterized and matched postmortem samples. These investigations have found reductions in glial cell number and density in frontal limbic cortical regions in BPD subjects [6–9]. The alterations in glia are accompanied by more subtle changes in the density and/or size of specific populations of neurons [6, 8, 9]. Specific types of neurons are also reduced in the hippocampal formation [10] and anterior cingulate cortex in BPD [11], whereas glial cells have not been systematically studied in hippocampus. Some studies indicate increases rather than reductions in the neuronal cell number in the hypothalamus [12, 13] and brain stem nuclei [14–16]. The alterations in cell number and density in BPD are likely to be related to the disorder itself and not to the age, postmortem delay, or time of tissue fixation, since statistical analyses conducted in all of the above-mentioned morphometric studies yielded no significant correlation between cell numbers and any of these confounding variables. It cannot be ruled out, however, that some of the cellular alterations in mood disorders are related to prior treatment with mood stabilizers [6]. Interestingly, postmortem anatomic findings indicate that cellular pathology in the dorsolateral prefrontal cortex (DLPFC) in schizophrenia and BPD differs in magnitude, direction, laminar scope, and relative involvement of neuronal and glial cell types [17].

22.3 POSTMORTEM NEUROCHEMICAL FINDINGS

Torrey et al. [18] summarize results obtained by 56 research groups that studied a single set of specimens (15 each with schizophrenia, BPD, major depression without psychosis, and unaffected control subjects) of the Stanley Neuropathology Consortium. One hundred RNA, protein, and other neurochemical markers were assessed in seven neurochemical systems. Quantitative measures of continuous variables for prefrontal, hippocampus, anterior cingulate, superior temporal cortex, or a combination of these were analyzed. Before correcting for multiple comparisons, 23% of the markers were abnormal in one or more regions, with most indicating decreased expression. Markers that reached statistical significant difference of $\geq 20\%$ and were specific for BPD are complexin 1 and 2 and glucocorticoid receptor in the subiculum, SNAP-25 in the stratum pyramidale, dopamine 5 receptor in the CA1 and the dentate, and synaptophysin and GAP43 in the anterior cingulate. The largest percentage of markers was associated with the developmental/synaptic and γ -aminobutyric acid (GABA) systems. Bipolar disorder and schizophrenia had a 65% overlap. All these findings await further replication in other brain banks.

Since lithium has powerful effects on cell signaling, signaling pathways have been studied as a possible neurochemical etiological abnormality in BPD postmortem brain [19–21]. The function of the phosphoinositide second-messenger system has been assessed in occipital, temporal, and frontal cortex obtained postmortem from subjects with BPD and matched control subjects by measuring the hydrolysis of phosphatidylinositol [22]. There was a selective impairment in the G-protein-stimulated phosphatidylinositol hydrolysis in occipital cortex from bipolar patients compared with control subjects, indicative of a possible impairment in G-protein function. The reason for the selective localization of the deficit is not known. While an initial study by Shimon et al. [23] of prefrontal inositol levels in BPD postmortem brain provided evidence for a reduction, this was not replicated [24]. Differences,

however, have been found in G-protein levels. Elevated levels of the long splice variant of the $G_s\alpha$ subunit were reported in frontal, temporal, and occipital cortices [25, 26] and in the thalamus [27] and of the short splice variant in the hippocampus and caudate nucleus of postmortem brain from BPD patients compared with controls. The long and short splice variants differ in their interaction with the β_2 adrenoceptor [28] and in their potency to activate adenylate cyclase [29], so that changes in their relative expression levels in BPD brain may have consequences for cyclic adenosine monophosphate (cAMP) signaling. However, the increase in $G_s\alpha$ protein levels has not been consistent across studies. It was replicated by Friedman and Wang [30], but not by Dowlatshahi and colleagues [31]. The basis for the discrepancies is presently unknown. It could stem from postmortem differences in clinical and demographic characteristics of the cohort studied, such as drug treatments, agonal state, and tissue-handling conditions. More and better controlled studies with larger sample size will be necessary to validate the changes in G-protein levels in BPD brain.

Within the context of G proteins, Rahman et al. [32] found significantly lower cAMP binding in the cytosolic, but not in the particulate, fractions of cerebral cortices, cerebellum, and thalamus of postmortem brain from BPD patients compared with matched controls, implying that protein kinase A (PKA) regulatory subunit abundance is reduced in BPD brain. Chang et al. [33] found higher protein levels of the regulatory and catalytic PKA subunits in the cytosolic fraction of the temporal cortex from postmortem BPD brains compared with matched controls, consistent with observations of significantly higher levels of basal and stimulated PKA activities and lower activation constant for cAMP in the cytosolic fraction of temporal cortex of bipolar patients compared with controls [34]. Because there is extensive cross regulation among different intracellular signaling pathways and an increasing body of evidence implicates abnormalities in other signal transduction systems in mood disorders, it may be that the disturbances found in the cAMP signaling cascade result from dysregulation of one or more of the signal transduction pathways with which it interacts.

Altered intracellular Ca^{2+} homeostasis in BPD [20] has been suggested to be trait dependent [35]. Ca^{2+} homeostasis affects cellular necrosis and apoptosis [36]. Thus, the elevated PKA subunit levels [33] and PKA activity [34] in postmortem BPD brain described above could reflect a neuroprotective response to processes affecting intracellular homeostasis in BPD.

Prefrontal cortex and cerebellar expression of reelin messenger RNA (mRNA), GAD protein and mRNA, and prefrontal cortex reelin-positive cells have been reported to be decreased by 30–50% in patients with schizophrenia and BPD with psychosis but not in those with unipolar depression without psychosis when compared with nonpsychiatric subjects. The results were, apparently, unrelated to neuronal damage, postmortem interval, dose, duration, or presence of antipsychotic medication. The selective downregulation of reelin and GAD67 in prefrontal cortex of patients with BPD who have psychosis was interpreted by the authors to be consistent with the hypothesis that these parameters are vulnerability factors in psychosis [37].

Abnormal expression of molecules critical for glutamatergic signaling in subcortical structures have been suggested to be associated with the pathophysiology of severe psychiatric illnesses including BPD. CGP39653 and MK-801 are analogs that

bind to the glutamate binding site and the open ion channel of the *N*-methyl-D-aspartate (NMDA) receptor, respectively. In subjects with bipolar disorder the density of MK-801 binding in the CA3 and in the pyramidal and the polymorphic layers of the subiculum and the density of CGP39653 binding across the hippocampal formation were found to be decreased [38]. The density of all GAD67 mRNA-containing neurons was decreased by 35% in layer 2 of the anterior cingulate cortex. The numerical density of GAD67-containing neurons that coexpressed NR(2A) [an NMDA receptor subunit] mRNA was 60% decreased in layer 2 in BPD. The expression level of NR(2A) mRNA in GAD67-containing cells was unaltered. It was concluded that the density of GABA interneurons that express the NMDA NR(2A) subunit is decreased in BPD [39]. Decreased striatal expression of transcripts encoding the postsynaptic density proteins PSD-95 and SAP-102 was found in bipolar disorder while no significant changes in the neurofilament (NF) subunit NF-L and in PSD-93 mRNAs were observed, suggesting dysregulation of cortical-subcortical circuitry [40].

The findings reviewed and others not covered in this chapter do not as yet converge into a comprehensive description of the pathophysiology of BPD. Even previous generalizations that postreceptor intracellular signaling abnormalities rather than pre- and postsynaptic receptor functioning are involved in the etiology of BPD [41] seem to have been premature.

22.4 IN VIVO NEUROIMAGING

The advantages of in vivo neuroimaging over postmortem studies include the avoidance of postmortem artifacts, reduction of long-term drug use artifacts, and the possibility of longitudinal studies that examine patients in all three states of the illness, that is, mania, depression, and euthymia, before and after treatment. However, the marked psychomotor changes in mania and depression may well cause secondary nonspecific brain changes. To our knowledge, no studies use control groups of normals told to overexercise as a control for mania or fasting and sleep restriction as a control for depression. For example, a recent paper using functional magnetic resonance imaging (fMRI) found increased amygdala activation in nine manic patients to a specific task in the left amygdala only. Patients were being medicated and the number of subjects was small [42]. Drevets [43] reported a seminal paper using both positron emission tomography (PET) and MRI reporting decreased grey matter and blood flow in the subgenual prefrontal cortex and abnormal responsiveness to emotional stimuli. This finding, which has a priori specificity, awaits replication. While it is disappointing that most of the in vivo neuroimaging findings are not corroborated by postmortem neuroanatomic data, functional imaging may be providing a more dynamic profile of brain regional dysfunction.

22.5 PERIPHERAL NEUROCHEMICAL FINDINGS

Numerous interesting abnormalities have been reported in peripheral tissues, especially blood cells, of BPD patients. None to our knowledge have been replicable by several groups, and few seem well integrated with postmortem findings or in vivo

neuroimaging. For instance, we reported decreased inositol monophosphatase (IMPase) activity in BPD lymphocytes [44] and were able to replicate this in a second sample and show specificity vis-à-vis schizophrenia and unipolar depression [45]. However, we could not find this decrease of IMPase activity in postmortem brain in BPD [45]. Yoon et al. reported abnormal intracellular Ca^{2+} in a subgroup of BPD patients in B-lymphoblast cell lines [46]. This finding awaits replication and could be related to numerous other abnormalities because of the central role of Ca^{2+} in intracellular signaling. Table 22.1 highlights and summarizes selected molecular and neuroanatomical findings in BPD.

22.6 MECHANISM OF ACTION OF LITHIUM

In 1999 the scientific community celebrated 50 years of lithium's use in the treatment of bipolar disorder. *Goodman & Gilman's Pharmacological Basis of Therapeutics* has been reviewing lithium for over 40 years. In the second edition (1958), lithium salts were claimed to have no therapeutic application and no biological function. They were described as a salt substitute in low-sodium diets where they were found to be toxic. The third edition (1965) recorded that lithium exhibits similar behavior to that of sodium in a number of biological systems, and it was first mentioned that lithium was used in the treatment of the manic phase of manic-depressive illness. The fourth edition (1970) noted that controlled clinical studies indicate that lithium is better than placebo in the prevention of manic disorders, but the mechanism whereby lithium has an effect in affective disorder is unknown. It was noted that lithium may decrease norepinephrine levels at critical receptor sites in the central nervous system (CNS). In the seventh edition (1985) the mechanism of action of lithium was still unknown but mention was made of a "little effect on catecholamine-sensitive adenylate cyclase activity," ligand binding to brain-adrenergic receptors, and a role in inhibiting the effect of receptor blocking agents to cause supersensitivity in adenylate cyclase.

In the eighth (1990) and ninth (1996) editions it was declared that the mechanism of action of lithium remains unknown, although this was now accompanied by the suggestion that biological membranes may be involved. The ninth edition (1996) discusses lithium's modification of hormonal responses as mediated by adenylate cyclase or phospholipase C, developing a transmission-modulation hypothesis of lithium's mechanism of action. In the tenth edition (2001), the mechanism of action of lithium as a mood stabilizer still remains unknown, although multiple cellular effects of lithium were characterized and enumerated. This edition also first describes common targets of lithium and valproate.

These findings may present an embarrassment of riches, since it is difficult to know which data, if any, may be related to mood-stabilizing action and which may be epiphenomena. Herein, we review some of the most prominent current work on the mechanism of action of lithium.

Lithium at therapeutic concentrations inhibits glycogen synthase kinase-3 (GSK-3) as does valproate. GSK-3 was found to be inhibited by lithium in two ways [55]. First, lithium directly inhibits the enzyme. This direct inhibitory effect is amplified in vivo by an increase in the inhibitory phosphorylation of an N-terminal serine in GSK-3, enabling low concentrations of lithium to significantly modulate GSK-3. Inhibition of GSK-3 by lithium has multiple effects on cellular functions due to the numerous

TABLE 22.1 Molecular and Neuroanatomical Findings in BPD

Finding	Tissue/Technique	Possible Implication	Reference
Postmortem Brain			
Reduced oligodendrocyte- and myelin-related gene expression	Gene array	Loss of myelin may lead to aberrant circuits controlling thoughts	[48]
Decreased hippocampal NMDA receptor number but not density	In situ radioligand binding	Altered information processing mediated by hippocampal glutamatergic function	[38]
Occipital cortex hypoaactive phosphatidylinositol (PI) signaling	³ H-PI hydrolysis	Decreased occipital cortex PI signal transduction	[22]
Decreased brain inositol	Cortex, gas chromatography	Deficient phosphatidylinositol second messenger signaling	[23]
Reduced glial density (fewer but larger cells) in cortex	Dorsolateral prefrontal cortex layer III; morphometric three-dimensional cell counting	Abnormal neurodevelopment without gliosis	[9]
Decrease in brain reelin	Prefrontal cortex and cerebellum; studied with immunohistochemistry, reverse transcriptase PCR and Western blotting	Brain extracellular matrix abnormality	[37]
Peripheral Tissue			
Decreased ZIP (Z-Pro-proline-insensitive peptidase) and PO (prolyl-oligopeptidase) in lithium-treated patients	Plasma	Altered cell signaling	[49]
Decreased platelet PLC (phospholipase C) and PKC (protein kinase C) activity and expression of some of isozymes; increased MARCKS (myristoylated alanine-rich C-kinase substrate) expression	Fractionation of cytosol and membranes; Western blotting	Deficient second-messenger signaling	[50]

TABLE 22.1 (Continued)

Finding	Tissue/Technique	Possible Implication	Reference
Increased intracellular Ca^{2+} in a subgroup of patients	Lymphoblastoid cell lines	Abnormal intracellular regulation	[46]
Reduced inositol and IMPase	Lymphoblastoid cell lines	Abnormal phosphatidylinositol second-messenger signaling	[51]
Increased platelet PIP_2 (phosphatidylinositol-4,5-bisphosphate)	Two-dimensional thin-layer chromatography	Impaired cell signaling	[52]
Lower <i>IMP42</i> (one of the two genes coding for IMPase) expression	Lymphoblastoid cell lines	Altered calcium signaling	[46]
Imaging			
Decreased gray matter and blood flow in subgenual prefrontal cortex	Magnetic resonance imaging and positron emission tomography in familial bipolar depressives	Abnormal emotional responsiveness to socially significant or provocative stimuli	[43]
Increased vesicular monoamine transporter (VMAT)	Thalamus and ventral midbrain; binding of VMAT2 by positron emission tomography in vivo	Increased serotonin innervation	[53]
Elevated gray matter lactate and γ -aminobutyric acid	Two-dimensional proton echo-planar spectroscopic imaging	A shift in energy redox state glycolysis > oxidative phosphorylation	[54]
Decreased cortical <i>N</i> -acetyl aspartate	Dorsolateral prefrontal cortex magnetic resonance spectroscopy in vivo	Decreased neuronal density or dysfunction	[83]

substrates of GSK-3, any of which may contribute to the mood-stabilizing action of lithium. These include regulation of neural plasticity through changes in cellular architecture and remodeling events, regulation of gene expression through modulation of the activities of transcription factors, and regulation of cellular responses to stress and the ensuing modulation of cell survival. Jope [55] suggests that the manifold influences of GSK-3 on the dynamics of neuronal function provide support for the proposal that GSK-3 is a key target for the therapeutic actions of lithium. GSK-3 β inhibitors are under development as treatments for Alzheimer's disease and diabetes, and those with an appropriate therapeutic index and pharmacokinetics may someday come to clinical trials in BPD.

Lithium has effects on transcriptional and posttranscriptional mechanisms that modulate the expression of a variety of genes possibly involved in aberrant signaling cascades or impaired cellular resilience implicated in the pathophysiological mechanisms underlying BPD [56]. Of particular note, the prophylactic properties of lithium in preventing recurrent episodes of mania and depression may be attributable to its chronic action in regulating the expression of key proteins in brain. The problem remains to distinguish between primary therapeutic properties linked to the action of lithium versus its secondary side-effect profile. New strategies using DNA chIp-chip technology to address this transcriptional activity of chronic lithium on genes encoding proteins such as PACAP, MARCKS, and cyclin-D, promise to help define a lithium-responsive gene network that will provide a foundation for pathway mapping of novel targets for the development of new drugs with more specific and efficacious mood-stabilizing properties [57]. Application of more recent genomic and proteomic approaches not only will offer improved therapeutic drugs but also will provide needed clues to the underlying etiology and pathophysiology of BPD.

Considerable preclinical and clinical evidence suggests that lithium has neuroprotective and neurotrophic effects which may have relevance for the mechanism of mood stabilization by lithium [58]. Lithium has been noted to have neuroprotective effects in cell culture and in animal models of neurodegeneration such as stroke, Huntington's disease, and Alzheimer's disease, possibly through regulation of expression and/or activity of molecules and enzymes involved in neuroplasticity, neuroprotection, and mitochondrial function, including Bcl-2, GSK-3, and the extracellular regulated kinase/mitogen-activated protein kinase (ERK/MAPK) pathway. Emerging clinical evidence additionally suggests that lithium may have similar effects in patients; these findings include an increase in *N*-acetyl aspartate (NAA) and gray matter in patients following long-term lithium treatment. The possibility that lithium enhances neurogenesis reflected in increased grey matter volume is intriguing but has not yet gained consensus. Among four papers by Soares's group two report confirmation [59, 60] and another two report negative replication [61, 62]. A recent comprehensive study [63] also failed to find statistically significant difference of grey matter and limbic volume in lithium-treated patients compared to controls. Moreover, neuroprotection seems to be a common property of many psychoactive compounds, including antipsychotics, antidepressants, and even nonpsychotropic compounds such as several antibiotics [64]. Thus neuroprotection by lithium in a variety of model systems may or may not be related to its mode of therapeutic action.

Chronic lithium may exert its therapeutic effects by normalizing aberrant phosphoinositide signaling through its interactions with inositol monophosphatase and the phosphoinositide pathway, downstream alterations in protein kinase

C (PKC) activity, and substrate phosphorylation [64]. McNamara and Lenox [65] have described that chronic, but not acute, lithium treatment at clinically relevant concentrations significantly reduces the expression of MARCKS (myristoylated alanine rich C-kinase substrate), a primary and preferential PKC substrate, and that MARCKS gene expression is regulated by chronic lithium at the transcriptional level through a lithium-responsive element in the MARCKS promoter. The MARCKS protein is located in pre- and postsynaptic terminals where it has been implicated in the regulation of phosphoinositide hydrolysis, filamentous-actin cytoskeletal plasticity, vesicular trafficking, and the release efficacy of several neurotransmitters. MARCKS is necessary for normal mouse brain development and remains highly expressed in several key adult cortical, limbic, and subcortical brain regions. Several neuroplastic events are sensitive to alterations in MARCKS expression, and prolonged elevations in PKC activity, physiological stress, and proinflammatory factors induce alterations in MARCKS expression. The long-term mood-stabilizing effect, as well as some side effects (memory impairment), of chronic lithium may stem from its capacity to down regulate MARCKS expression and/or modulate its phosphorylation in dysregulated circuits.

Lithium inhibition of adenylate cyclase (AC) has been known for several decades but has not developed into a platform for new drug development [66]. Lithium's effect on this system would have been expected to result in widespread undesired effects in multiple tissues. However, the cloning and biochemical characterization of 10 (AC1–AC9 and SAC) nonclustered AC isoforms distributed among different chromosomes revealed that the different isoforms also have distinct regulatory properties [67, 68] so that the characteristics of the response in a given cell depends on the AC isoform(s) present in the cell [69–72]. Within the brain, AC isoforms localize to discrete regions and show differential regulation by Ca and by G-protein subunits; for example, AC1 and AC3 are expressed in hippocampus, and neocortex, stimulated by Ca-calmodulin, and thereby could be activated by NMDA and involved in synaptic plasticity. High AC2 expressions appear in the hippocampus, hypothalamus, and cerebellum and moderate ones in neocortex, piriform cortex, and amygdala. AC4 is often referred to as “striatal adenylyl cyclase.” AC5 seems to be associated uniquely with dopamine innervation. AC5 and AC6 (also enriched in brain) are inhibited by physiological Ca concentrations. AC7 brain levels are low [67]. Future discovery of differing thresholds for lithium inhibition among the isoforms may pave the way for the AC hypothesis to be revisited.

Chuang [73] studied the protective effect of long-term lithium treatment against glutamate-induced, NMDA receptor-mediated, excitotoxicity in primary cultures of rat brain neurons. The neuroprotective effects of lithium are accompanied by a reduction in NMDA receptor-mediated calcium influx, upregulation of the anti-apoptotic mitochondrial protein Bcl-2, downregulation of proapoptotic p53 and Bax, and activation of the cell survival signaling pathway. In addition, lithium antagonizes glutamate-induced activation of c-Jun N-terminal kinase (JNK), p38 kinase, and AP-1-binding and suppresses glutamate-induced loss of phosphorylated cAMP response element binding protein (CREB) due to activation of protein phosphatase-1. In addition, lithium induces BDNF and activates its receptor TrkB in cortical neurons, which may be implicated in the putative neuroprotective effects of this drug. In a rat stroke model, post-insult treatments with therapeutic doses of lithium or valproate markedly reduce ischemia-induced brain infarction and

neurological deficits. These neuroprotective effects are associated with suppression of caspase-3 activation and induction of chaperone proteins. In a rat excitotoxicity model of Huntington's disease in which an excitotoxin was infused into the striatum, both long- and short-term pretreatment with lithium reduces excitotoxin-induced DNA damage, caspase-3 activation, and striatal neuronal loss. This neuroprotection is associated with upregulation of Bcl-2 in neurons. Lithium also induces cell proliferation near the injury site with a concomitant loss of proliferating cells in the subventricular zone. Some of these proliferating cells display neuronal or astroglial phenotypes. This finding corroborates in vitro results showing that lithium stimulates the proliferation of neuroblasts in primary cultures of CNS neurons.

Inositol depletion is an acute response to lithium [74] and valproate [75], and aberrant inositol metabolism has been reported in bipolar patients [76]. The role of inositol as a metabolic sensor for the secretory, unfolded protein response and glucose response pathways suggests that treatment with inositol-depleting drugs may lead to dramatic changes in complex cellular processes [77]. One such recent example is a study by Brandish et al. [78], wherein the authors report highly significant upregulation of the expression of a hypothalamic peptide (PACAP) mediator of monoamine signaling and circadian rhythm in rat brain slices exposed to chronic lithium at clinically relevant concentrations under myo-inositol-limiting conditions. Genetic, molecular, and biochemical studies in yeast for over three decades have elucidated intricate mechanisms underlying regulation of inositol biosynthesis in this model eukaryote. *INO1*, the gene encoding 1D-myo-inositol 3-phosphate (MIP) synthase, is the most highly regulated of the genes required for phospholipid biosynthesis. This enzyme, which catalyzes the rate-limiting step in inositol biosynthesis, is highly conserved from yeast to humans. The human *INO1* gene is functional in yeast and complements the inositol deficiency of the yeast *ino1* mutant. Similar to the yeast enzyme, human MIP synthase activity is decreased in the presence of valproate [79]. Because inositol is a metabolic sensor for a variety of signal transduction pathways, MIP synthase may represent a target for new mood-stabilizing drugs.

22.7 MECHANISM OF ANTICONVULSANT ANTIBIPOLAR COMPOUNDS

Anticonvulsant drugs such as valproate, carbamazepine, and lamotrigine possess antibipolar properties in the clinical setting. Their mechanism in epilepsy most probably involves voltage-activated sodium channels, but effects on GABA, on NMDA receptors, on K^+ channels, and on calcium channels may also be involved in some drugs of this class [80]. Attempts to look for commonalities between lithium and the anticonvulsant antibipolar drugs may be heuristic; however, there may be serious pitfalls as well. For instance, lamotrigine may have efficacy preferentially in the treatment of bipolar depression, lithium appears to have proconvulsant properties in some animal models, and the evidence for long-term efficacy in preventing recurrent episodes of mania and depression may vary among these drugs. As noted earlier and described below, ongoing studies are identifying molecular pharmacological properties that may converge under further investigation. Furthermore, in our future explorations, we should be cautious regarding previously accepted assumptions. For instance, phenytoin in the past was used as a negative control in

biochemical experiments identifying pathways for mood stabilizers, but recent clinical work suggests that this may not be the case [81, 82].

Using a differential display polymerase chain reaction (PCR), Wang and Young found [47] that chronic treatment with valproate at a therapeutically relevant concentration increased expression of 78-kDa glucose-regulated protein (GRP78), an endoplasmic reticulum (ER) stress protein, in rat brain. Chronic valproate treatment increased not only GRP78 mRNA level but also GRP78 gene transcription and protein levels. Chronic treatment with lithium also increased GRP78 mRNA and protein levels in primary cultured rat cerebral cortical cells. Unlike the classic GRP78 inducer thapsigargin, an inhibitor of the ER Ca^{2+} -ATPase, both lithium and valproate moderately increase GRP78 expression in neuronal cells without affecting basal intracellular free Ca^{2+} concentration and cell viability, indicating that these two drugs increase GRP78 expression without causing cell stress. Since GRP78 exhibits molecular chaperone activity, binds calcium, folds damaged proteins, and has been shown to inhibit oxidative stress and apoptosis, their findings corroborate the notion that both lithium and valproate generate a neuroprotective effect against cell damage. Expression of two other closely related ER stress proteins, GRP94 and calreticulin, has also been shown to increase by chronic treatment with lithium and valproate. One may wonder, however, whether upregulation of stress-induced proteins is not merely a nonspecific response to the aversive effect of the drugs.

22.8 CONCLUSION

Despite all the information presented in this chapter, the statement that “the biochemical basis for mood stabilizer therapies or the molecular origins of bipolar disorder is unknown,” which appears in all editions of the Goodman and Gilman textbook and in most of the reviews on mood stabilization and BPD in recent years, is still true. It is highly likely that many of the biochemical findings regarding the mechanism of action of lithium will be found to represent components of pathways that play a role in the pathophysiology of BPD. As noted above, some of these may be shared with the anticonvulsants possessing antibipolar properties. As the allegory of the blind men and the elephant would suggest, at best we are merely looking at parts of the whole. On the other hand, the ultimate understanding of the pathways contributing to the long-term prophylactic action of drugs like lithium in the treatment of BPD is expected to lead to a better understanding of the pathophysiology of BPD and a rational basis for the development of novel antibipolar drugs in the future. In addition, the current advances in neuroimaging for both PET and MRI offer an ideal opportunity to utilize convergent data from our molecular pharmacological studies that will provide promising insights into the underlying neurobiology of this disease.

PREFACE

Neuropharmacology is the study of drugs that affect the nervous system. This includes not only the identification of neuronal drug targets but also the study of basic mechanisms of neural function that may be amenable to pharmacological manipulation. Indeed, neuropharmacological drugs are commonly used as valuable tools to discover how nerve cells function and communicate in addition to therapeutic agents for the treatment of a wide variety of neuropsychiatric disorders. In fact, drugs that are used to treat disorders of the brain and nervous system represent one of the largest groups of approved therapeutic agents. Clearly the demand for drugs to treat disorders of the nervous system will only grow in the face of an aging population. Not surprisingly, almost all major pharmaceutical corporations and many biotechnology companies have extensive drug discovery programs in neuroscience and neuropharmacology. The recent pace of research and discovery in neuropharmacology and associated therapeutics has been quite rapid, as is true for most areas of biomedical research. Given this as well as the extremely broad nature of the field, we felt that it would be timely and important to develop a comprehensive handbook of neuropharmacology that would include state-of-art reviews covering both basic principles and novel approaches for clinical therapeutics.

Our approach for the organization of this handbook was primarily translational (bench to bedside) in nature. The three book volumes consist of 10 clinical sections, each consisting of 4–7 chapters devoted to various neuropsychiatric disorders, including mood, anxiety, and stress disorders, psychosis, pain, neurodegeneration, and many others. In most cases, these sections have introductory chapters providing background information and/or basic principles prior to presenting chapters covering state-of-the-art therapeutics. Volume I also contains a large introductory section consisting of 17 chapters on basic neuropharmacological subjects and principles. These include chapters on the history of neuropharmacology as well as intercellular and intracellular signaling followed by chapters covering all of the major neurotransmitter systems and other important signaling molecules, such as ion channels and transporters. Our objective for this project was to create a high-level reference work that will be useful to all practitioners of neuropharmacology ranging from graduate students, academicians, and clinicians to industrial scientists working in drug discovery. These volumes will be part of the John Wiley & Sons major reference work program and will be published online as well as in print. The online version of this handbook is expected to undergo frequent updates and additions in order to maintain its cutting-edge status.

The editors would like to thank all of the chapter contributors for their hard work and commitment to this project. We would also like to thank our managing editor, Jonathan Rose, at John Wiley & Sons for all of the valuable assistance that he has provided.

Preface	xi
Contributors	xiii

VOLUME 1

PART I BASIC NEUROPHARMACOLOGY	1
Chapter 1 Soup or Sparks: The History of Drugs and Synapses	3
<i>William Van der Kloot</i>	
Chapter 2 Synaptic Transmission: Intercellular Signaling	39
<i>J. David Jentsch and Robert H. Roth</i>	
Chapter 3 Synaptic Transmission: Intracellular Signaling	59
<i>R. Benjamin Free, Lisa A. Hazelwood, Yoon Namkung Michele L. Rankin, Elizabeth B. Rex, and David R. Sibley</i>	
Chapter 4 Neuronal Nicotinic Receptors: One Hundred Years of Progress	107
<i>Kenneth J. Kellar and Yingxian Xiao</i>	
Chapter 5 Muscarinic Acetylcholine Receptors	147
<i>Jürgen Wess</i>	
Chapter 6 Norepinephrine/Epinephrine	193
<i>Megan E. Kozisek and David B. Bylund</i>	
Chapter 7 Dopaminergic Neurotransmission	221
<i>John A. Schetz and David R. Sibley</i>	
Chapter 8 Serotonin Systems	257
<i>John A. Gray and Bryan L. Roth</i>	
Chapter 9 Neuropharmacology of Histamine in Brain	299
<i>Raphaël Faucard and Jean-Charles Schwartz</i>	

Chapter 10	Ionotropic Glutamate Receptors	365
	<i>David Bleakman, Andrew Alt, David Lodge, Daniel T. Monaghan, David E. Jane, and Eric S. Nisenbaum</i>	
Chapter 11	Metabotropic Glutamate Receptors	421
	<i>James A. Monn, Michael P. Johnson, and Darryle D. Schoepp</i>	
Chapter 12	Pharmacology of the GABA_A Receptor	465
	<i>Dmytro Berezhnoy, Maria C. Gravielle, and David H. Farb</i>	
Chapter 13	Metabotropic GABA Receptors	569
	<i>Martin Gassmann and Bernhard Bettler</i>	
Chapter 14	Voltage-Gated Ion Channels	617
	<i>Alex Fay, Patrick C. G. Haddick, and Lily Yeh Jan</i>	
Chapter 15	Neuropeptides	669
	<i>Fleur L. Strand</i>	
Chapter 16	Neurotransmitter Transporters	705
	<i>Jia Hu, Katherine Leitzell, Dan Wang, and Michael W. Quick</i>	
Chapter 17	Gaseous Signaling: Nitric Oxide and Carbon Monoxide as Messenger Molecules	743
	<i>Kenny K. K. Chung, Valina L. Dawson, and Ted M. Dawson</i>	
PART II	MOOD DISORDERS	763
Chapter 18	Neurobiology and Treatment of Depression	765
	<i>Alexander Neumeister, Dennis S. Charney, Gerard Sanacora, and John H. Krystal</i>	
Chapter 19	Neurotrophic Factors in Etiology and Treatment of Mood Disorders	789
	<i>Ronald S. Duman</i>	
Chapter 20	Antidepressant Treatment and Hippocampal Neurogenesis: Monoamine and Stress Hypotheses of Depression Converge	821
	<i>Alex Dranovsky and René Hen</i>	
Chapter 21	Neuroendocrine Abnormalities in Women with Depression Linked to the Reproductive Cycle	843
	<i>Barbara L. Parry, Charles J. Meliska, L. Fernando Martinez, Eva L. Maurer, Ana M. Lopez, and Diane L. Sorenson</i>	
Chapter 22	Neurobiology and Pharmacotherapy of Bipolar Disorder	859
	<i>R. H. Belmaker, G. Agam, and R. H. Lenox</i>	
Index		877
Cumulative Index		915

VOLUME 2

PART I	ANXIETY AND STRESS DISORDERS	1
Chapter 1	Neurobiology of Anxiety	3
	<i>Miklos Toth and Bojana Zupan</i>	
Chapter 2	Pharmacotherapy of Anxiety	59
	<i>Jon R. Nash and David J. Nutt</i>	
Chapter 3	Benzodiazepines	93
	<i>Hartmut Lüddens and Esa R. Korpi</i>	
Chapter 4	Neuroactive Steroids in Anxiety and Stress	133
	<i>Deborah A. Finn and Robert H. Purdy</i>	
Chapter 5	Emerging Anxiolytics: Corticotropin-Releasing Factor Receptor Antagonists	177
	<i>Dimitri E. Grigoriadis and Samuel R. J. Hoare</i>	
Chapter 6	Neurobiology and Pharmacotherapy of Obsessive-Compulsive Disorder	215
	<i>Judith L. Rapoport and Gale Inoff-Germain</i>	
PART II	SCHIZOPHRENIA AND PSYCHOSIS	249
Chapter 7	Phenomenology and Clinical Science of Schizophrenia	251
	<i>Subroto Ghose and Carol Tamminga</i>	
Chapter 8	Dopamine and Glutamate Hypotheses of Schizophrenia	283
	<i>Bitá Moghaddam and Houman Homayoun</i>	
Chapter 9	Molecular Genetics of Schizophrenia	321
	<i>Liam Carroll, Michael C. O'Donovan, and Michael J. Owen</i>	
Chapter 10	Postmortem Brain Studies: Focus on Susceptibility Genes in Schizophrenia	343
	<i>Shiny V. Mathew, Shruti N. Mitkus, Barbara K. Lipska, Thomas M. Hyde, and Joel E. Kleinman</i>	
Chapter 11	Pharmacotherapy of Schizophrenia	369
	<i>Zafar Sharif, Seiya Miyamoto, and Jeffrey A. Lieberman</i>	
Chapter 12	Atypical Antipsychotic Drugs: Mechanism of Action	411
	<i>Herbert Y. Meltzer</i>	

PART III	SUBSTANCE ABUSE AND ADDICTIVE DISORDERS	449
Chapter 13	Introduction to Addictive Disorders: Implications for Pharmacotherapies	451
	<i>Mary Jeanne Kreek</i>	
Chapter 14	Dopaminergic and GABAergic Regulation of Alcohol-Motivated Behaviors: Novel Neuroanatomical Substrates	465
	<i>Harry L. June and William J. A. Eiler II</i>	
Chapter 15	Nicotine	535
	<i>August R. Buchhalter, Reginald V. Fant, and Jack E. Henningfield</i>	
Chapter 16	Psychostimulants	567
	<i>Leonard L. Howell and Heather L. Kimmel</i>	
Chapter 17	MDMA and Other “Club Drugs”	613
	<i>M. Isabel Colado, Esther O’Shea, and A. Richard Green</i>	
Chapter 18	Marijuana: Pharmacology and Interaction with the Endocannabinoid System	659
	<i>Jenny L. Wiley and Billy R. Martin</i>	
Chapter 19	Opiates and Addiction	691
	<i>Frank J. Vocci</i>	
PART IV	PAIN	707
Chapter 20	Neuronal Pathways for Pain Processing	709
	<i>Gavril W. Pasternak and Yahong Zhang</i>	
Chapter 21	Vanilloid Receptor Pathways	727
	<i>Makoto Tominaga</i>	
Chapter 22	Opioid Receptors	745
	<i>Gavril W. Pasternak</i>	
Chapter 23	Advent of A New Generation of Antimigraine Medications	757
	<i>Ana Recober and Andrew F. Russo</i>	
	Index	779

1.1 INTRODUCTION

“Anxiety” is the subjective feeling of heightened tension and diffused uneasiness. It is a normal reaction to threatening situations and serves a physiological protective function in eliciting avoidance behaviors. The majority of individuals respond to anxiety-evoking environment appropriately but with some individual differences. The range of appropriate responses to threatening situations can best be described by individual differences in personality traits, in particular in emotional (in)stability/neuroticism [1–3]. Both genetic and environmental factors contribute to emotional (in)stability and to personality traits in general [4]. Approximately 5–10% of individuals display an exaggerated response to real or perceived threat or interpret ambiguous situations as threatening and can be classified as suffering from anxiety disorders [5]. It may be conceptualized that these individuals lie outside of the normal range of individual differences in emotional (in)stability [6]. Indeed, emotional instability and anxiety share common genetic factors.

Although a genetic contribution to emotional instability (neuroticism) and anxiety has long been known, it is only recently that multipoint linkage analysis identified chromosomal regions that may harbor candidate genes [7, 8]. Also, genetic polymorphisms in the serotonin (5-HT) transporter (5-HTT), 5-HT_{1A} receptor, and brain-derived neurotrophic factor (BDNF) have recently been associated with neuroticism and anxiety conditions [9–11]. The slow pace of discovering susceptibility genes in human is largely due to the complex genetics of personality traits and common disorders; thus, individual genes have a relatively small contribution to traits/diseases. The effect of the environment on the expression of anxiety disorders also complicates the elucidation of the underlying pathogenic processes.

Animal models have long been used in the research of anxiety. Quantitative trait locus (QTL) analysis suggests that the genetic basis of “emotionality”/fear reaction in mice can be defined as the variance of a set of few behavioral measures [12–15], such as avoidance of novel environment (abbreviated in this review as Av), behavioral inhibition/activity in highly or moderately threatening situations (Ac) and autonomic arousal (Aa). These dimensions of rodent behavior are reminiscent of the characteristics of emotional instability/neuroticism in humans. In the last decade, a large number of induced mutations have been generated by homologous recombination in the mouse, and some of these strains show a significant deviation from their parental strain in measures of fear response. The abnormal fear response of these mice can be conceptualized as anxiety-like, similar to anxiety disorders in humans. By analyzing a large number of these strains and by classifying them according to the three fundamental dimensions of noncognitive behavior proposed above (AvAcAa), it is possible to implicate multiple neurobiological processes in anxiety-like behavior. Furthermore, these genetic models allow the study of the combined effect of two or more genes as well as the interaction of genes and environment in the expression of anxiety-like behavior in mice. These results may be extrapolated to humans and they eventually could help to better understand the polygenic and multifactorial nature of human anxiety disorders.

1.2 PSYCHOLOGICAL TRAITS AND THEIR GENETIC BASIS

Since anxiety is the continuous expression of normal human personality traits, it is important to briefly summarize a few of the leading personality theories. Personality

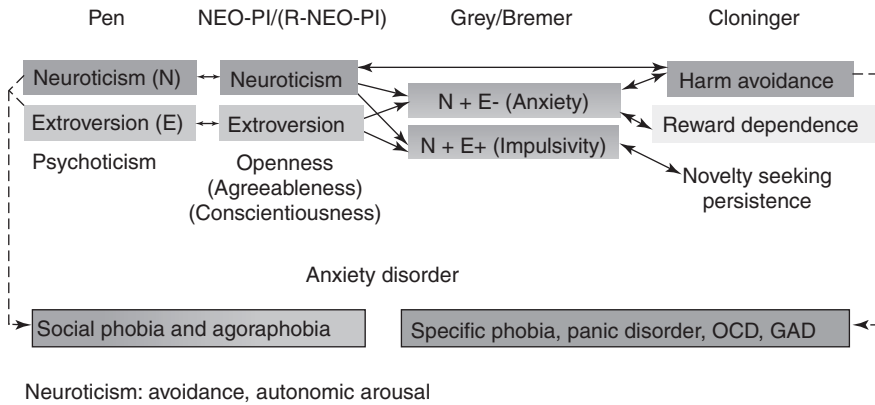

Figure 1.1 Psychological traits and models. According to various models, personality consists of three to five fundamental traits. Arrows indicate corresponding traits in the various models. Traits are highly variable in individuals, but most individuals fall in between the extremes of a trait. Behavior outside of this range can be considered abnormal. For example, higher than normal level of neuroticism (in the PEN model) or harm avoidance (in the Cloninger model) is characteristic for anxiety disorders. (See color insert.)

traits are underlying characteristics of an individual that can explain the major dimensions of human behavior. Traits are dimensions representing a continuum of characters and most people fall in between the extremes. Personality traits have a wide individual variation, but they are relatively stable in individuals over time [16]. Cognitive/intellectual and noncognitive/affective/psychological traits are two fundamental domains of personality. Although the separation of the cognitive and noncognitive domains of personality may be practical, these variables interact and influence each other. Among the psychological traits two, extroversion versus introversion (E) and emotional stability versus instability or neuroticism (N), are probably the most important. An additional dimension is psychoticism (P) in the PEN model [1, 2] (Fig. 1.1). Autonomic arousal is an integral part of neuroticism and it is characterized by increased heart rate and blood pressure, cold hands, sweating, and muscular tension. A similar system based on the broad traits of neuroticism, extroversion, and openness is the NEO personality inventory (NEO-PI) [3]. Other models hypothesize the existence of more than three fundamental traits. The Big 5 (B5) model has three other dimensions in addition to emotional stability and extroversion [17–19]. The revised (R) NEO-PI also has five factors, and besides neuroticism, extroversion, and openness, consists of the factors of agreeableness and conscientiousness [20] (Fig. 1.1). NEO-PI-R is a self-report inventory with a high retest reliability, item validity, longitudinal stability, consistent correlations between self and observer ratings, and robust factor structure that has been validated in a variety of populations and cultures [3]. Gray [21] has modified Eysenck's PEN model by rotating the dimensions of neuroticism and extroversion by 45°, resulting in two new dimensions: anxiety (N +, E –) and impulsivity (N +, E +). Gray's work, however, has been done mostly on animals. Still another personality assessment is Cloninger's biosocial model, which conceptualizes temperament as consisting of the four genetically and biochemically distinct traits of harm avoidance, reward

dependence, novelty seeking, and persistence [22] (Fig. 1.1). Harm avoidance is correlated with NEO-PI-R neuroticism. Reward dependence is related to the anxiety/neuroticism/extroversion traits of other classifications (Fig. 1.1). Novelty seeking is also related to these traits and is similar to impulsivity in the Gray hypothesis. Each of these broad dimensions of personality is comprised of a number of smaller traits which are narrower in scope.

Using the techniques of quantitative behavioral genetics, it became clear that roughly 40–60% of the variation in most personality traits has a genetic base. Broad personality traits are under polygenic influence [4, 23]. Recently, genomewide linkage studies have been performed by using the EPQ (Eysenck personality questionnaire) [1, 2] to identify chromosomal regions associated with neuroticism. A two-point and multipoint nonparametric regression identified 1q, 4q, 7p, 8p, 11q, 12q, and 13q [7], while another similar study using multipoint, nonparametric allele sharing and regression identified 1q, 3centr, 6q, 11q, and 12p [8], confirming some of the linkages in the previous study.

1.3 EXTRAPOLATION OF PSYCHOLOGICAL TRAIT OF NEUROTICISM TO MOUSE BEHAVIOR

1.3.1 Emotionality as Measure of Avoidance, Behavioral Inhibition/Activation, and Autonomic Arousal in Animals

Behavioral studies with various rodent strains indicate that a set of a few behavioral measures can describe “emotionality,” a behavior similar to the psychological traits of emotional instability/neuroticism in humans [12–15]. To be able to analyze and compare a large number of animal studies, we have selected throughout this review three commonly used measures of emotionality: avoidance of novel environment, activity/behavioral inhibition in highly or moderately threatening situations, and autonomic arousal (Fig. 1.2). Here we refer to this triad of behavioral measures as AvAcAa (avoidance, activity, and arousal).

1.3.2 Quantifying Emotionality in Animals

Attempts to measure emotionality and stress response in rodents have yielded a large number of tests [24–28]. Ten years ago it was estimated that there were over 30 such tests in use [29], and modifications of earlier tests have likely increased this number since then. Initially, the development of these tests was facilitated by the need of preclinical identification and characterization of anxiolytics. Indeed, these tests are often referred to as anxiety tests, anxiety-related tests, or animal models of anxiety, even if most of them actually measure the normal reaction of animals to novelty and stress.

The animal models measure either unconditioned or conditioned fear/anxiety-like behaviors. Another classification is based on more specific behaviors such as social and defensive behavior. Table 1.1 provides a short list of the more commonly used tests while more thorough reviews of the assays can be found elsewhere [28–32]. Unconditioned exploration tests measure the natural conflict experienced by animals to either explore a novel environment for food, water, or social reward or avoid it due

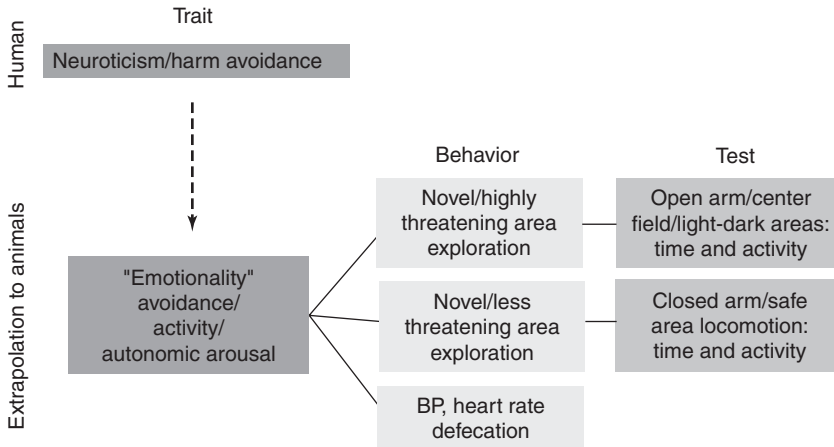

Figure 1.2 Measures of “emotionality” in rodents. The human trait of neuroticism is extrapolated to the measures of emotionality in rodents: avoidance, activity, and autonomic arousal (AvAcAa). AvAcAa can be quantified in well-established behavioral models. Exploration of a low and a moderate to highly threatening environment provides measures of avoidance and activity, while physiological functions provide measurements of autonomic arousal. (See color insert.)

TABLE 1.1 Commonly Used Animal Tests of Anxiety

Conditioned tests	<i>Punishment-Induced:</i> Geller–Seifter conflict, Vogel punished drinking	<i>Fear:</i> fear-potentiated startle, contextual/cued fear conditioning, passive/active avoidance	
Unconditioned tests	<i>Exploration:</i> elevated-plus and zero mazes, open field, light–dark box	<i>Social Interactions:</i> maternal separation, social competition	<i>Other:</i> acoustic startle, hyponeophagia, defense test batteries, shock-probe burying

to potential unknown dangers. Measurements of avoidant behaviors, such as decreased exploration of a particular region of the testing apparatus, compared to overall locomotor activity provide a quantifiable measure to assess the level of conflict in such novel environments. In a laboratory setting, animals are introduced into a novel and more or less fearful environment and their avoidance, behavioral inhibition/activity, and autonomic responses are measured. For example, the elevated-plus maze (EPM) [33] consists of a cross with opposing pairs of arms which are either open or enclosed and is elevated above the ground. The normal rodent behavior is to prefer the enclosed compartment of the maze, which is less aversive. During normal exploratory activity, however, the animal will enter the open arms. These entries into and the time spent in the open arms are counted and used to assess the level of avoidance, although additional, more complex behaviors can also be

recorded [33]. The elevated-zero maze (EZM) is a modification of the EPM where the four arms have been replaced by a circular track separated into four quadrants of alternating open and enclosed regions. Avoidance can also be assessed in the center of a brightly lit open field [34]. Animals tend to stay and move around the periphery of the field, since the open area and bright illumination are aversive. The avoidance measured in an open field is assessed by the number of entries into and the time spent in the center of the open field or the path length in this area. An adaptation of this test is the light–dark crossing task [35], consisting of a two-compartment box in which one area is dark and the other is brightly lit. This test uses the animals' natural tendency to prefer the dark and to avoid the brightly lit area. In this case, the number of crosses into and the time spent in the light compartment reflect the level of avoidance. Most studies compare the open arm/light compartment/center field activity/time as a percent of total activity/time. Also, exploration in the less aversive areas of the test apparatus (closed arm/dark compartment, periphery of the open field) is often regarded as an assessment of general activity levels, and it has been proposed that avoidance in the more stressful areas cannot be interpreted unless locomotor activity in low-stress areas is normal [36]. However, out-of-cage test environments are stressful even if they are moderately threatening. This notion is supported by the finding that a QTL has been linked to both the suppression of general locomotor activity and high-stress-area avoidance in a study involving a large number of mice [15]. Therefore, a number of laboratories, including ours, prefer to score overall locomotor activity separately (e.g., in activity boxes) as one measure of emotionality [37, 38]. The EPM, open field, and light–dark box tests are viewed as straightforward and relatively simple tests to conduct and as such are frequently used. However, more complex methods which highlight different aspects of avoidant behavior are available but are less commonly used. For example, in the social interaction test, behavior such as sniffing, grooming, mounting, and contact are monitored and used to infer changes in emotionality [39].

Conditioned conflict tests assess punishment-induced avoidance of a conditioned behavior. The Geller–Seifter test [40] is based on the conflict between completing an appetitive conditioned response that is unexpectedly paired with an unpleasant stimulus, such as the delivery of a mild electric shock. The Vogel punished drinking test [41] is similar to the Geller–Seifter test but does not require an extensive training period for the conditioning of the measured response. In the Vogel punished drinking test, the subject is water deprived for 12–24 h and then placed into a testing apparatus containing a water bottle with a spigot from which the animal can drink. Thirsty subjects learn quickly that water is available from the spigot and will readily drink from it when repeatedly placed into the testing apparatus. During the test session, however, the water spigot is connected to an electrical source that provides a mild electric shock upon contact with the spigot, placing the animal in conflict of choosing the appetitive reward or avoiding it. The level of avoidance reflects the emotionality of the subject.

Emotionality can also be measured in conditioned fear paradigms [42] such as fear-potentiated startle and contextual fear conditioning. These tests involve the element of emotional learning, as a neutral stimulus such as sound or light is paired with an electric foot shock. After a few trials, the previously neutral stimulus becomes aversive when presented alone. Mobility and freezing time can be used as indices of behavioral inhibition. A similar test is passive/active avoidance, a

one-pairing fear-induced avoidance assay. An animal is placed into a compartment and it has to either remain in that compartment to avoid a mild shock (passive avoidance) or go to another compartment (active avoidance, or escape-directed behavior) to avoid the aversive stimulus. Overall, conditioned tests provide less between-subject baseline variability than unconditioned response tests, but most conditioned assays require extensive training and the use of additional groups for controlling potential differences in learning and memory.

1.4 ANXIETY: CONTINUOUS EXPRESSION OF NORMAL HUMAN PERSONALITY TRAITS

It has long been proposed that the underlying structure of normal adaptive traits and the maladaptive personality traits of anxiety are the same [22]. Analysis of normal personality traits by NEO-PI in persons with psychiatrist-ascertained anxiety disorders in a general population showed an association of high neuroticism with lifetime anxiety disorders [simple phobia, social phobia, agoraphobia, panic disorder, obsessive-compulsive disorder (OCD), and generalized anxiety disorder] (Fig. 1.1). Social phobia and agoraphobia were also associated with low extroversion, and OCD was associated with high openness to experience [43]. In the Cloninger model, anxiety incorporates many aspects of harm avoidance [22]. Autonomic arousal, an integral part of neuroticism, is also a characteristic of anxiety disorders and is manifested as tachycardia, increased blood pressure, and elevated core temperature [44].

Recent genetic studies further support the notion that anxiety is the continuous expression of certain personality traits. For example, neuroticism/harm avoidance share a common genetic variant with susceptibility to anxiety disorders. Lesch et al. demonstrated that a functional 5-HTT promoter polymorphism is associated with the NEO-PI-R factor neuroticism and harm avoidance of the Cloninger model [9]. Extension of these genetic studies to anxiety disorders by the same authors showed no differences in 5-HTT genotype distribution between anxiety patients and comparison subjects, but among anxiety patients, carriers of a specific 5-HTT allele exhibited higher neuroticism scores than noncarriers [45]. Over 20 other studies investigated this association, and recent meta-analyses of these studies found a small but significant association between 5-HTT polymorphism and in some but not all measures of neuroticism/anxiety [46]. These studies remind us of the multifactorial nature of anxiety and that individual genes have only a small contribution to the clinical phenotype.

1.4.1 Anxiety Disorders

In the United States, anxiety disorders are most often defined and diagnosed according to a categorical system established by the **Diagnostic and Statistical Manual of Psychiatric Disorders**, currently in its fourth edition (DSM-IV) [5]. The DSM-IV sets the boundary at which a particular level of emotionality becomes an anxiety disorder—a level often based on the number and duration of observable symptoms of anxiety. This categorical model of anxiety, although necessary for the clinical diagnosis of anxiety disorders, is far from being reflective of the biological

nature of emotional states. Emotionality and anxiety are more realistically illustrated through a dimensional model that encompasses a continuum of various measures. The subjectivity of diagnosis is further illustrated by the marked differences in the diagnostic criteria of generalized anxiety disorder between the DSM-IV [5] and the ICD-10 Classification of Mental and Behavioral Disorders [47]. Although a core group of symptoms is identical in the two systems, DSM-IV relates these symptoms to vigilance while ICD-10 emphasizes the importance of autonomic arousal/hyperactivity. For the purpose of the present review, a quick overview of the DSM-IV classifications of anxiety disorders will be presented, while further discussions on different diagnostic criteria of DSM-IV and ICD-10 can be found elsewhere [48, 49].

The DSM-IV provides diagnostic criteria for a number of anxiety disorders, including panic disorder, specific and social phobias, OCD, posttraumatic stress disorder (PTSD), and generalized anxiety disorder [5, 50]. Individuals suffering from panic disorder experience recurrent and unexpected panic attacks which lead to discrete periods of intense fear and/or discomfort. Panic attacks are characterized by increased autonomic responses, including increased heart and breathing rates, sweating, nausea, abdominal distress, chills or hot flashes, and lightheadedness. Panic disorder may include agoraphobia, defined as the avoidance of places or situations in which escape may be difficult or embarrassing in the event of a panic attack. Specific and social phobias are marked by persistent fear of either clearly discernible objects or situations or potentially embarrassing social or performance situations, respectively. Exposure to the phobic stimulus almost invariably leads to heightened anxiety that may be expressed as a panic attack. Phobic stimuli are most often actively avoided. OCD features recurrent obsessions and compulsions severe enough to interfere with everyday life. Obsessions are described as persistent and inappropriate anxiogenic ideas, thoughts, or impulses that are unrelated to a real-life problem. Individuals suffering from OCD reduce obsession-induced anxiety by performing repetitive behaviors known as compulsions. These excessive and stereotypic behaviors or mental acts are not realistically connected with what they are designed to neutralize (i.e., washing and cleaning, counting, checking, and rearranging, etc.). PTSD can develop following a traumatic event involving feelings of intense fear, helplessness, or horror (e.g., military combat, rape, assault, and serious accident). Patients experience distressing recollection of the event, numbing of general responsiveness, and persistent arousal. They make deliberate and persistent efforts to avoid trauma-associated stimuli. Finally, generalized anxiety disorder is characterized by persistent (over six months) and excessive worry, inability to control worry, muscle tension, irritability, and sleep disturbance that are not necessarily related to a specific threatening situation. Many individuals also experience somatic symptoms (dry mouth, sweating, nausea, urinary frequency) that are reminiscent of certain symptoms of panic attacks [5].

1.4.2 Anxiety-Like Behavior in Animals

Studying rodent behavior in various anxiety-related test paradigms (see Section 1.3.2) reveals variation in emotionality in these species [51–53]. This includes variability in avoidance of aversive environment (Av), activity/behavioral inhibition in highly or moderately threatening situations (Ac), and autonomic arousal (Aa)

Figure 1.3 The three dimensions (AvAcAa) of emotionality in rodents in three-dimensional representation. Avoidance (Av) is plotted on the x axis, the positive spectrum representing increased levels of avoidance in stress-inducing environments or following stress-inducing stimuli and the negative spectrum representing attenuation of avoidance or even increased risk-taking behavior. Activity (Ac) as a response to stress and fear is plotted on the y axis, with the positive spectrum corresponding to increased levels of activity in a moderate to highly stressful environment. Following habituation, the activity is not different. Decreased activity in such an environment would be plotted in the negative spectrum of the y axis. Finally, the z axis is used for autonomic arousal (Aa) elicited by fearful or stressful stimuli, including increased heart rate, increased blood pressure, heightened levels of muscle tension (as measured by the startle response), defecation, and urination. A positive or negative deviation from the normal level of autonomic arousal can be represented by the positive and negative spectra of this axis, respectively. The normal range of these measures in a population is represented by the gray cube. Increased anxiety-like behavior can be conceptualized as increased avoidance, reduced activity, and increased arousal beyond the normal range of variations, denoted by the red area of the cube. Reduced anxiety-like behavior or increased novelty-seeking/risk-taking behavior is characterized by attenuation of avoidance, increased activity, and reduced autonomic arousal, highlighted by the blue area of the cube. (See color insert.)

(Fig. 1.2). Figure 1.3 displays these three basic characteristics as dimensions that together determine the degree of emotionality (see gray box for the range of normal variation of the three dimensions).

Many selectively bred and genetically modified mouse/rat strains show significant deviations from the normal variability of these dimensions. Once measures of behavior in mutant rodents exceed the threshold of variance of the normal/control

population (increased avoidance, reduced activity, and increased autonomic arousal), the resulting condition can be conceptualized as anxiety-like and similar to anxiety disorders in humans (Fig. 1.3; see red area of the cube). Emotionality can also be decreased (attenuation of avoidance, increased activity, and attenuated autonomic arousal) in a novel environment (Fig. 1.3; see blue area of the cube). Indeed, individual animals with higher and lower emotionality have been selected from a population and bred selectively to obtain strains characterized with high and low anxiety-like behavior. The Maudsley reactive inbred rat strain shows a stable and reproducible deficit in exploratory behavior as compared to the Maudsley non-reactive strain [54]. A similar breeding strategy based on behavior in the EPM test (open arm entries and time) resulted in the high-anxiety-related behavior (HAB) and low-anxiety-related behavior (LAB) rat lines [55]. These differences in behavior presumably reflect contributions from multiple genetic loci. Since generating induced mutations in mice has become routine, numerous mutant strains with either increased or decreased anxiety-like phenotype have been identified (see detailed description of these lines in Section 1.8.2).

Mutant mice with increased emotionality/fear reactions can be used as models of anxiety, and it is important to determine if they have construct and face validity. The criterion of construct validity requires that the rationale used to form the animal model is based on the etiology and the biological factors of anxiety. Construct validity criteria are difficult to fulfill because factors underlying the human disorders are largely unknown. However, in a few cases, the animal model has a genetic defect similar to that identified in anxiety disorders. For example, reduced expression of the 5-HT_{1A} receptor has been repeatedly shown in anxiety disorders and mice heterozygous for the inactivated 5-HT_{1A} receptor have an increased anxiety-like phenotype (see Sections 1.6 and 1.10).

Face validity represents a similarity in the physiological and behavioral measures observed in humans and in the animal model. As with construct validity, some animal models meet this criterion more easily than others. Physiological expressions of fear as well as anticipation of fear are comparable across species as they include easily quantifiable autonomic or endocrine responses such as increases in heart rate, blood pressure, body temperature, and muscle tension or changes in plasma corticosterone.

Predictive validity refers to the sensitivity of the model to clinically effective pharmacotherapeutic drugs. Benzodiazepines, for example, are commonly used in the treatment of anxiety; hence, a proposed animal model with predictive validity should show decreased measures of anxiety following benzodiazepine administration. In contrast, anxiogenic compounds should produce the opposite in physiological and behavioral measures. In addition, compounds with no effect in the clinic should not alter these measures in an animal model. Although predictive validity is an essential criterion for an animal model of anxiety in preclinical research, it has less relevance in studies focusing on the pathogenesis of anxiety disorders. Indeed, sensitivity to anxiolytics such as benzodiazepines varies in the population [56, 57]. For example, it has been shown that subjects high in neuroticism [58] and panic disorder patients [59–61] are less sensitive to benzodiazepines, with true benzodiazepine treatment resistance occurring in up to 24% of panic patients [62]. A similar difference in drug response can also be seen in certain animal models of anxiety such as the 5-HT_{1A} receptor-deficient mouse strains on various genetic backgrounds [38].

1.5 FEAR/ANXIETY CIRCUITS

1.5.1 Brain Regions Related to Anxiety Disorders

Anxiety is an emotion involving a complex interaction among many interconnected brain regions, with each component playing a specific role [63]. Most of these brain regions are part of the basic fear network, which is comprised of the prefrontal cortex, hippocampus, thalamus, and amygdala and its projections to brain regions responsible for coordinating the behavioral, autonomic, and endocrine response to fear (i.e., ventral tegmental area, locus ceruleus, dorsal motor nucleus of the vagus, nucleus ambiguus, lateral hypothalamus, paraventricular nucleus of the hypothalamus, etc.). Imaging technologies such as positron emission tomography (PET), magnetic resonance imaging (MRI), and functional MRI (fMRI) have made a large impact on elucidating the roles of various fear pathway structures in anxiety disorders. One of the best characterized limbic structures for its role in processing fear-related stimuli is the amygdala [64–66]. Furthermore, neuroimaging studies have shown that abnormal amygdala function is involved in anxiety disorders. Excess amygdala activation has been observed in PTSD patients in response to stimuli reminiscent of the traumatic event [67, 68] as well as in specific phobia patients when exposed to a phobia-related stimulus [69]. A volumetric MRI study revealed a significantly lower bilateral amygdala volume in panic disorder patients compared to individuals in the healthy control group [70]. Abnormal amygdala volume is not specific to panic disorder, as reduced amygdala volume has also been observed in patients suffering from OCD [71]. In contrast, larger right amygdala volume was measured in generalized anxiety disorder patients [72]. However, this particular study was performed in children; thus age, in addition to different anxiety diagnosis, may explain the contradicting results. Interestingly, the same cohort of children was later followed up with an fMRI study in which an exaggerated right amygdala response to fearful faces was observed in generalized anxiety disorder patients but not in healthy children. These results are suggestive of a relationship between structure and function and indicate that hyperactivity of the amygdala may be a characteristic feature of some anxiety disorders [73].

In addition to the hyperactivity of the amygdala, a number of neuroimaging studies have reported functional abnormalities in other fear pathway substrates in anxiety disorder patients. For example, increased levels of activity were found in the orbitofrontal cortex, hippocampus, and anterior and posterior cingulate in response to directed imagery of strongly emotional personal experiences in subjects suffering from panic disorder compared to healthy individuals [74]. Exaggerated activation of the orbitofrontal cortex has also been documented in specific phobia patients [69]. In contrast, the anterior cingulate gyrus showed lower levels of activity in PTSD during exposure to emotional stimuli by several groups [72, 75–77]. The anterior cingulate abnormality, together with the observed hyperactivity of the amygdala, has been incorporated into a neuroanatomical model of PTSD. Medial prefrontal structures, including the cingulate cortex, are thought to inhibit the activity of brain regions involved in fear responses, and therefore a hypoactive medial prefrontal cortex would fail to inhibit the amygdala in this model of PTSD [77, 78].

The hippocampus has also been extensively studied by neuroimaging techniques. Volumetric imaging studies that have been performed on PTSD patients have yielded

conflicting results with regard to hippocampal size. Some have found no differences in hippocampal volume between PTSD patients and non-trauma-exposed controls [79, 80], while others have documented either unilateral or bilateral reduction in hippocampal volume in PTSD patients [81–84]. A fundamental problem with most imaging studies is that the correlation between size of a neural substrate and the disorder in which it is documented may not be causal. In an attempt to address this issue, Wignall et al. [83] measured the hippocampal volume of recent-onset PTSD patients and found a decrease in right-sided hippocampal volume. Although the authors could not exclude the possibility that the hippocampal damage occurred during the time between the traumatic event and the onset of PTSD (mean of 158 days), they leaned toward the interpretation that smaller hippocampal volumes predispose individuals to the development of PTSD. A similar, yet longitudinal MRI study, however, showed that survivors of traumatic events who developed PTSD had no differences in hippocampal volumes at one week and at six months following the trauma when compared to trauma survivors that did not develop PTSD [80]. This particular controversy was somewhat abated by a study that found that monozygotic twins of PTSD combat veterans who themselves were not exposed to combat showed comparable hippocampal volumes to their combat-exposed brothers and that the hippocampi of these twins were significantly smaller than those of both combat veterans without PTSD and their non-combat-exposed twins [81]. These results indicate that a smaller hippocampal volume is a pre existing PTSD predisposing factor rather than a product of the disorder. A reduced hippocampal volume is not, however, a prerequisite for the development of the disorder.

Certain dopaminergic substrates, particularly the ventral striatum, have been found to be both larger in volume [85] and functionally hyperactive in patients suffering from OCD. Other hyperactive regions documented include orbitofrontal cortex, caudate, thalamus, and the anterior cingulate cortex [85, 86]. Based on these data the prevailing hypothesis of OCD pathogenesis proposes that OCD symptoms are mediated in part by a defect in the orbitofrontal-subcortical circuits.

1.5.2 Brain Regions Related to Emotionality/Anxiety-Like Behavior in Animals

Brain regions involved in fear and emotionality in animals are largely the same as those implicated in anxiety disorders (Fig. 1.4). The amygdala has a central importance in the acquisition, retention, and expression of conditioned fear [87–89]. The amygdala seems to function as an emotional/cognitive interface receiving sensory information via projections from the cortex and the thalamus. Outputs from the amygdala to the frontal cortex are related to the conscious perception of fear while outputs to the locus ceruleus, hypothalamus, periaqueductal grey, and striatum mediate autonomic, neuroendocrine, and skeletal-motor responses associated with fear and anxiety.

Although it is widely accepted that the hippocampus plays an important role in certain forms of learning and memory, recent studies have shown that the hippocampus is also involved in fear and emotionality. Interestingly, ventral hippocampal lesions affect anxiety while dorsal lesions result in defects in spatial learning. For example, cytotoxic lesions of the ventral hippocampus resulted in reduced aversion in the center of the open field, reduced freezing after footshock, and reduced inhibition in novelty-suppressed feeding [90]. Also, lesion of the ventral but not dorsal

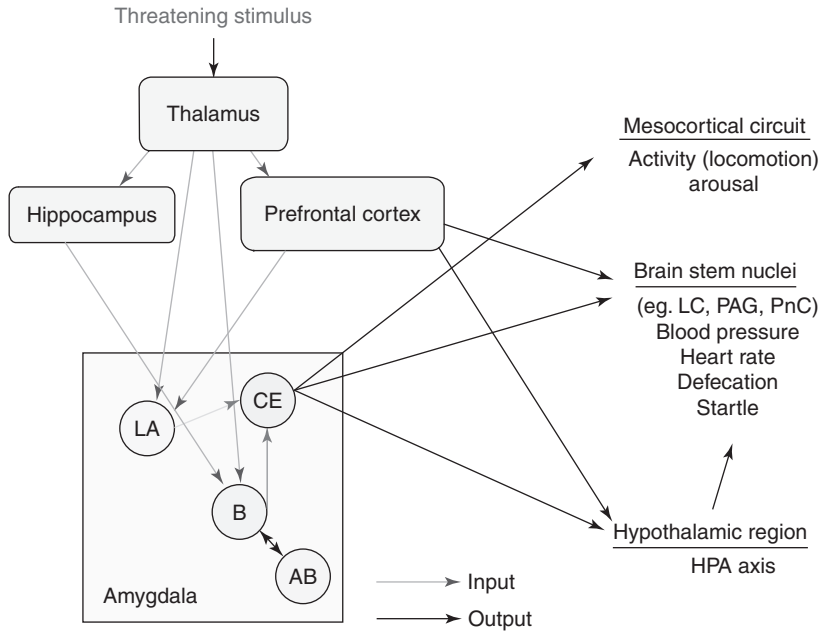

Figure 1.4 Brain regions involved in processing fear, stress, and emotionality in animals. Threatening stimuli are received and processed by brain regions such as the thalamus, hippocampus, prefrontal cortex (PFC), and amygdala. The amygdala sends projections to a number of target regions. These include brain stem nuclei such as the locus ceruleus (LC), periaqueductal gray (PAG), and pontine nucleus caudalis (PnC), which mediate various forms of autonomic arousal. The amygdala is also connected to the mesocortical circuit that mediates arousal and activity (as measured by locomotion in mice) and the hypothalamic region which controls glucocorticoid levels through the hypothalamic–pituitary–adrenal (HPA) axis. The PFC, which is involved in executive functions such as attention, also sends projections directly to the brain stem and the hypothalamus. (See color insert.)

hippocampus increased open-arm exploration in EPM [91, 92]. The septohippocampal system has been identified as being essential for the sensory processing of stimuli based on novelty and punishment [93]. Hippocampus has also been implicated in contextual fear conditioning [94].

Forebrain structures, including the medial prefrontal cortex (MPFC) and septum, are connected to the limbic system and their dysfunction has also been found in anxiety. Also, several studies have shown that lesions (cytotoxic and transection) of the MPFC inhibit fear-related behavior in rats [95–98]. These data indicate that MPFC promotes anxiety-like behavior. Finally, brain stem nuclei are important in the regulation of arousal. Of particular importance in anxiety are the noradrenergic locus ceruleus and the serotonergic raphe nuclei [99, 100].

1.6 NEUROTRANSMITTER SYSTEMS AND NEURONAL MESSENGERS IMPLICATED IN ANXIETY AND ANXIETY-LIKE BEHAVIOR

Traditionally, anxiety disorders have been viewed as disturbances in neurotransmitters, including γ -aminobutyric acid (GABA), 5-HT, norepinephrine (NE), dopamine

(DA), and neuropeptides such as corticotropin-releasing hormone (CRH), cholecystokinin (CCK), and neuropeptide Y (NPY). Many of these neurotransmitters and their receptors have been identified as sites of action for anxiolytic drugs. However, neuronal messengers other than neurotransmitters such as cytokines have recently been implicated in anxiety. Here we summarize the relevant pharmacological data while a later section covers the pertinent genetic studies.

Alterations in GABA_A receptor function have long been implicated in anxiety disorders. For example, a deficit in GABA_A receptors has been identified in the hippocampus and parahippocampus of patients suffering from panic disorder and generalized anxiety disorder [101–103]. Furthermore, GABA_A receptor antagonists can elicit anxiety in patients with panic disorder, thereby mimicking a functional deficit of GABA_A receptors [104]. The GABA_A receptor is a pentameric ion channel typically composed of 2 α (α_{1-6}), 2 β (β_{1-3}), and 1 γ (γ_{1-3}) subunits [105, 106], and animal studies suggest that alterations in specific GABA_A receptor subunits are associated with certain forms of anxiety, such as withdrawal-induced anxiety [107, 108]. GABA_A receptor subunits have an especially important relevance in terms of the anxiolytic effect of benzodiazepines [109–111]. Classical benzodiazepines exert their effects by binding to multiple subtypes of GABA_A receptor, the predominant subtypes in the brain being those that contain $\alpha_{1,2,3,5}$ subunits. A recent report using receptor subtype–preferring compounds in nonhuman primate models concluded that α_1 subunits containing receptors do not play a key role in the anxiolytic and muscle-relaxant properties of benzodiazepine-type drugs; instead, these effects involve $\alpha_{2,3,5}$ subunits containing GABA_A receptors [112]. Animal models have recently also been used to determine the GABA_A receptor subtype involved in the anxiolytic action of benzodiazepines (see description of these animals in Section 1.10).

Although lesion of 5-HT neurons in animals suggests a role for 5-HT in the control of anxiety states [113], the evidence for this notion is both conflicting and controversial. On the other hand, pharmacological manipulation of either the 5-HTT or the 5-HT_{1A} receptor can clearly alter 5-HT neurotransmission and anxiety. The level of 5-HT is regulated by both the 5-HTT and the 5-HT_{1A} autoreceptor (in the serotonergic raphe nuclei) [114, 115]. Inhibiting 5-HTT by selective serotonin reuptake inhibitors (SSRIs) has been shown to be very effective in certain anxiety disorders [114, 115]. Also, partial 5-HT_{1A} receptor agonists such as buspirone have an anxiolytic effect [116]. Recently, animals with genetic modifications have significantly contributed to our understanding of the 5-HT system and the possible role of various 5-HT receptors in anxiety (see Section 1.10).

The role of NE in anxiety is based on its well-known involvement in stress reaction. Stress provokes and aggravates anxiety by increasing catecholamine release via the sympathoadrenal system in the periphery. In addition, NE neurons in the locus ceruleus play a critical role in the body's response to alarm and threat. NE is believed to play an especially important role in anxiety disorders, such as panic disorder and PTSD [117, 118].

DA is mostly known as a mediator of reward and locomotor activity. However, these processes are also fundamental in personality traits and emotionality (Figs. 1.1–3), and the pharmacological manipulation of DA receptors have been reported to modulate anxiety-related behaviors. Specifically, agonists and

antagonists for the DA D₂ class of receptors (which includes D₂, D₃, and D₄ subtypes) have anxiogenic and anxiolytic properties, respectively [119–121].

A number of neuropeptides have been implicated in anxiety and have been suggested as therapeutic targets [122]. The stress response is mediated partly by the activation of CRH. CRH is produced in the hypothalamus (H), leading to the secretion of the adrenocorticotropin hormone (ACTH) from the pituitary (P), which in turn causes an increase in the synthesis and release of glucocorticoids from the adrenal glands (A) (HPA axis). The activation of the HPA axis is also involved in stress-related psychopathology such as anxiety disorders [123–125]. The maladaptive effects of chronic stress on the HPA axis have been extensively studied in both preclinical and clinical settings, and since a number of excellent reviews are available, this topic is not discussed further here [125–129]. In addition to the activation of the HPA axis and the consecutive release of the stress hormones, CRH is present outside of the hypothalamus where it is believed to participate in stress response [130]. Central administration of CRH in rodents produces behavioral effects that correlate with a state of anxiety such as reduced exploration in a novel environment or enhanced fear response [131–134]. Preclinical studies strongly implicate a role for central CRH, probably via the central noradrenergic systems, in the pathophysiology of certain anxiety disorders [125].

Glucocorticoids (corticosterone in rodents and cortisol in humans), the final effectors modulating the physiological response to stress, act via two receptor subtypes: the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR) [135]. GRs are also the main regulators of a negative-feedback circuit that regulates the HPA axis following stress. Activation of GRs in the pituitary, hypothalamus, hippocampus, and frontal cortex decreases CRH gene expression, leading to a decrease in CRH release and the suppression of the stress-induced endocrine response [136, 137].

Another neuropeptide, NPY, has also been suggested to be involved in the clinical symptoms of anxiety [138]. In rats, central administration of NPY produces effects similar to that of anxiolytic drugs [139] whereas specific inhibition of the NPY-1 receptor by antisense oligonucleotide resulted in an increased anxiety-like behavior [140].

During the last few years, CCK has emerged as an important polypeptide in the central nervous system (CNS). There are several lines of evidence for a role of CCK in anxiety and panic attacks, and data also indicate that specific agonists to brain CCK(2) receptors produce anxiogenic-like effects while CCK(2) antagonists elicit anxiolytic-like responses [141–144].

Substance P has also been suggested to have a modulatory role in anxiety [145]. Substance P is released in response to aversive stimuli [146] and its administration in animal models elicits both anxiogenic and anxiolytic activity, depending on the dose and the specific brain region [122]. The receptor for substance P is the G-protein-coupled tachykinin NK-1 receptor which is expressed in brain areas associated with fear and anxiety [147]. Increasing numbers of reports indicate that specific antagonists of NK-1 receptors produce anxiolytic effects [148].

Although cytokines are not neurotransmitters and their primary role is in the immune system, several lines of evidence indicate that interleukin (IL) 1 β , interleukin-6, and tumor necrosis factor (TNF) α modulate anxiety and mood [149].

Specifically, these proinflammatory cytokines elicit symptoms of anxiety/depression that may be attenuated by chronic antidepressant treatment. Also, immunotherapy using IL-2 or interferon (IFN) α , promotes depressive/anxiety symptoms [149]. Interestingly, the effects of cytokines are exacerbated by stressors, and chronic cytokine elevations may act synergistically with stressors [149].

1.7 GENETIC SUSCEPTIBILITY TO ANXIETY DISORDERS

A number of studies have sought to identify chromosomal regions and genes relevant to anxiety disorders. Although the results of linkage and association studies are inconsistent so far (see detailed description of these studies in [150–152]), candidate gene studies have yielded more consistent data. In several studies, a relatively small but significant increase in neuroticism was found in individuals who carry the *s/s* (short promoter repeat) alleles of the 5-HTT as compared to individuals with *s/l* (long) or *l/l* alleles [9, 153]. The *s* allele is associated with decreased transporter activity. Over 20 other studies extended this association to psychopathology, but not all found evidence for an association between 5-HTT polymorphism and anxiety [45]. However, recent meta-analyses of these studies found a moderate but significant association between 5-HTT polymorphism and NEO neuroticism [46] and TPQ (tridimensional personality questionnaire) harm avoidance [154]. The association of decreased transporter activity with anxiety is a rather surprising finding because pharmacological inhibition of the 5-HTT by SSRIs reproducibly results in an anxiolytic effect. However, the genetically determined reduction in 5-HTT activity in patients is present from early prenatal life and may affect brain development leading to anxiety in later life. Consistent with this notion, pharmacological inhibition of 5-HTT in early postnatal life in mice (which corresponds to late prenatal life in human) resulted in increased anxiety-like behavior in later life [155]. In summary, these data suggest that genetic or pharmacological reduction of transporter activity during brain development can lead to increased anxiety in adult life.

The 5-HT_{1A} receptor (5-HT_{1A}R) has also been implicated in anxiety because reduced receptor levels were detected in the anterior cingulate, posterior cingulate, and raphe by positron tomography in patients with panic disorder [156]. These recent data complement previous reports that showed a deficit in the 5-HT_{1A}R in PTSD and panic disorder patients [157–160]. However, no specific 5-HT_{1A}R allele has been associated with anxiety disorders (a promoter polymorphism, on the other hand, has been linked to major depression and suicide [159]).

Although polymorphism in BDNF has primarily been studied in depressive disorder, the *val* allele of the Val66Met substitution polymorphism has recently been shown to be associated with higher mean neuroticism scores in the NEO- five factor inventory (NEO-FFI) in healthy subjects [161]. In another study the self-ratable state-trait anxiety inventory (Spielberger state-trait anxiety inventory) score, which allows anxiety to be quantified as a comparatively stable personality trait, showed a higher level of anxiety in Val/Val compared to Val/Met and Met/Met genotypes [11, 162]. These are surprising findings since it is the *met* allele that is hypofunctional (as a result of alterations in BDNF trafficking and secretion [163])

and because animal studies clearly show that genetic inactivation of BDNF results in anxiety (see Section 1.9).

1.8 GENETIC BASE OF ANXIETY-LIKE BEHAVIOR IN MICE

1.8.1 QTL Studies

QTL analysis of F2 hybrids of two strains of mice (A/J and C57BL/6J) that differ markedly in thigmotaxis and light-to-dark (LD) transition behaviors showed a linkage of LD to chromosome 10 (near D10Mit237; LOD of 9.3) and suggestive QTLs (LOD > 2.8) at chromosomes 6, 15, 19, and X [14]. In the open field, suggestive QTLs were mapped to chromosomes 6 and 14 [13]. These data indicate a lack of shared QTLs of fear/anxiety-associated behavior in various experimental paradigms (avoidance in LD and open field). Another group using multiple measures of avoidance and autonomic arousal found that the various measures are mapped to the same or nearby chromosomal location(s) [12, 15]. These studies used two relatively closely related mouse lines bred for differential anxiety-like behavior; thus a relatively small subset of genes may have changed during breeding. In contrast, the study that concluded a lack of shared QTLs in anxiety-like behavior [13] utilized the more distantly related A/J and C57BL/6J mice which presumably carried different anxiety-related alleles in multiple loci. This study may be easier to extrapolate to human populations characterized by a high degree of heterogeneity. So far, no genes have been identified in anxiety-related QTLs. Since QTLs are in the range of 10–30 cM, a region containing hundreds of genes, identification of linked genes within QTLs is difficult.

1.8.2 Anxiety-Like Behavior in Genetically Altered Mice

Recently, it has become possible to inactivate specific genes routinely in the mouse, and a large number of knockout strains have been generated. Many of the targeted genes have been implicated in anxiety, and the corresponding knockout strains have regularly showed behavioral abnormalities in anxiety-related tests (Tables 1.2 and 1.3). Beyond the mouse strains with inactivated “candidate” anxiety genes, anxiety-like behaviors were sometimes seen in mice with genetic inactivation in genes not obviously related to anxiety. These genes include intracellular signaling molecules and regulators of transcription/translation (Table 1.4). The association of these genes with anxiety-like phenotype indicates that anxiety is not limited to abnormalities of the neurotransmitter systems but can also be related to gene regulatory processes. Analysis of the genomic position of these genes shows that they are distributed throughout many chromosomes with no obvious clustering at any locus (Fig. 1.5).

One caveat of the analysis of anxiety-related knockout mouse strains is that the behavioral phenotypes are not always robust and are sometimes even questionable. Moreover, many variables can alter the interpretation of anxiety-related behavioral tests and tests are not standardized across laboratories and environmental factors. Furthermore, anxiety-like behavior may be part of a complex phenotype and secondary to major developmental or neuroanatomical defects. We limited our

analysis to mutant strains that have been generated and studied by multiple groups and to those that, although analyzed by a single laboratory, showed anxiety-related phenotypes in at least two independent behavior tests.

1.9 KNOCKOUT MICE WITH DISTURBANCES IN NEURONAL MESSENGERS EXHIBITING ALTERATIONS IN ANXIETY-LIKE BEHAVIOR

Classical neurotransmitters (GABA, NE, 5-HT) and neuropeptides have long been implicated in anxiety, so it was not surprising that inactivation of genes encoding enzymes responsible for the synthesis and metabolism of neurotransmitters or encoding neuropeptides alter anxiety levels (Table 1.2).

Glutamic acid decarboxylase (GAD) catalyzes the synthesis of GABA from glutamate and the genetic inactivation of the 65-kDa isoform of GAD (GAD65) results in anxiety-like behavior in mice [164]. Although GAD65 is responsible for the synthesis of a smaller pool of GABA than GAD67 [165, 166], it is associated with nerve terminals and synaptic vesicles and can be rapidly activated in times of high GABA demand. In GAD65^{-/-} tissues the overall GABA content is normal but K⁺-stimulated GABA release is reduced. Therefore, GAD65^{-/-} mice show no overt developmental phenotype but the more subtle anxiety-like behavioral phenotype [164] and increased seizure sensitivity [165]. In contrast, GAD67^{-/-} mice, although born at the expected frequency, die of severe cleft palate during the first morning after birth [166]. These data are consistent with reports that enhancing synaptic GABA levels, for example by GABA reuptake inhibitors, has an anxiolytic effect [167] and indicate that an appropriate level of synaptic GABA release is important for maintaining normal behavioral responses in anxiety-inducing situations.

The enzyme catechol-*O*-methyl transferase (COMT) is involved in the degradation of DA, NE, and epinephrine and its inactivation also leads to anxiety-like behavior [168]. Measurement of tissue catecholamine levels in COMT^{-/-} mice showed a specific increase in DA levels with no change in NE or 5-HT levels. Furthermore, this increase in DA seems to be restricted to the frontal cortex. Although the increased DA levels were evident in both males and females, an increased anxiety behavior was observed only in females.

Genetic inactivation of the NE transporter (NET), as expected, results in a significant increase of extracellular levels of NE [169]. These mice show increased activity in the open field that would be consistent with a reduced level of anxiety. However, no data are available regarding avoidance and autonomic arousal of these mice and hyperactivity can arouse independently of a change in anxiety.

Since 5-HTT (*s/s* genotype) has been identified as a susceptibility gene for anxiety (see Section 1.7), it was expected that mice with an inactivated copy of the corresponding gene would show elevated levels of anxiety. Initial studies indicated that knockout mice have no obvious behavioral phenotype even if 5-HTT binding sites were completely absent in these animals [170]. However, a later study indicated an increased anxiety-like phenotype in 5-HTT knockout mice which was more pronounced in females [171]. A more recent analysis of these mice found no differences in anxiety-related behaviors in the open-field and EPM tests, but an increase was seen in latency to feed in a novel environment [172]. Lack of a reproducible and robust anxiety-like phenotype in 5-HTT knockout mice raises the

question of how a partial reduction in 5-HTT activity in humans (*s/s* genotype) can be associated with elevated levels of neuroticism and anxiety.

Pharmacological experiments indicate the involvement of neuropeptides in the pathogenesis of anxiety, and this notion has been further supported by genetically modified mouse strains. An anxiety-like phenotype has been described in transgenic mice overexpressing CRH [173, 174]. However, mice with a deleted CRH gene did not differ from wild-type animals in anxiety-related behaviors even if they had significantly decreased basal corticosterone levels [175, 176]. One possible explanation is the redundancy in the central CRH system (e.g., urocortin). Consistent with this notion, stress-induced behavioral effects in CRH mutant mice could be reduced by the administration of a CRH antagonist [177]. Two independent groups have generated mice with a deletion of the urocortin gene [178], but only one study found behavioral abnormalities, namely an increased anxiety-like phenotype [178]. Finally, deletion of the CRH binding protein (BP), which normally binds and inactivates CRH, resulted in increased anxiety [179]. The authors hypothesized that the inactivation of CRH-BP may increase the “free” or unbound levels of CRH or urocortin, which results in anxiety. These data are also consistent with the reduced anxiety-like phenotype of mice constitutively overexpressing CRH-BP in the anterior pituitary gland [180].

Mice lacking the gene for NPY show a decrease in central area activity in the open field and an increased reactivity to acoustic startle [181]. However, no change in EPM was seen in NPY^{-/-} mice compared to controls, suggesting that the absence of the peptide results in a condition characterized by increased stress responsiveness rather than anxiety.

Apart from altered pain responses, preproenkephalin-deficient mice exhibit increased anxiety in the open field and EZM [182]. It is believed that the modulatory role of enkephalins on anxiety behavior may be mediated by the GABA system [183].

Consistent with the anxiolytic activity of orphanin FQ/nociceptin (OFQ/N) or selective synthetic agonists in rodents, OFQ/N knockout mice display increased anxiety in several anxiety-related tests and impaired adaptation to repeated stress [184, 185]. Increased plasma corticosterone levels and a failure to show stress adaptation of OFQ/N knockout mice may suggest that activation of the HPA axis contributes to the anxiety phenotype in these mice.

BDNF, a member of the family of neurotrophins, promotes the formation, maturation, and stabilization of both glutamatergic and GABAergic synapses during CNS development, and it therefore regulates the balance between excitatory and inhibitory transmission, a fundamental step in neural circuit formation [186, 187]. Although homozygote BDNF knockout mice die during the second postnatal week [180, 188], heterozygote or conditional knockout mice show signs of altered emotional behavior. The role of BDNF in emotional reactions is important because the *val* allele has been associated with predisposition to anxiety disorders [10, 11]. Heterozygote BDNF knockout mice showed a slower escape behavior in the learned helplessness paradigm after training as compared to wild-type mice [189]. However, this effect may have been due to reduced sensitivity to centrally mediated pain as BDNF is essential for the survival and maintenance of peripheral sensory neurons [180, 188]. On the other hand, conditional BDNF mutant mice have also shown other signs of anxiety-like behavior [190]. In these conditional knockout mice, BDNF was removed after birth when most neurons are postmitotic, suggesting that the

abnormal behaviors are related to neuronal maturation, survival, and/or plasticity rather than to the absence of BDNF during behavioral testing. Recently a mouse strain was generated in which the *val* allele was replaced by the *met* allele [190a]. Met substitution for Val in *BDNF* is a common polymorphism in humans associated with alterations in brain anatomy and memory. In agreement with association studies [10], BDNF(Met/Met) mice exhibited increased anxiety-related behaviors indicating that this variant predisposes to anxiety disorders.

In agreement with the anxiogenic effect of intracerebroventricularly administered TNF α in the EPM [191], transgenic mice overexpressing TNF α show less exploration in novel environment [192] and increased activity [193]. However, TNF α knockout mice have a similar behavior in the EPM [193, 194]; thus, the role of TNF in the regulation of emotionality is not clear. Lack of another cytokine, IFN γ , has been reported to cause an anxiety-like phenotype [195]. However, the expression of this phenotype was visible only in C57BL/6 but not in the BALB/c mouse strain, indicating that major genetic modifiers play a role in the manifestation of anxiety in these mice. IFN γ is involved in regulating the growth of axodendritic processes, raising the possibility that, similar to the BDNF knockout mice, a neurodevelopmental abnormality underlies the anxiety in these knockout mice.

1.10 KNOCKOUT MICE WITH DEFICITS IN NEUROTRANSMITTER RECEPTORS AND OTHER CYTOPLASMIC MEMBRANE-ASSOCIATED PROTEINS EXHIBITING ANXIETY-LIKE BEHAVIOR

Blocking GABA $_A$ receptor increases anxiety-like behavior and genetic inactivation of some of the subunit genes has a similar effect (Table 1.3). For example, heterozygote $\gamma_2^{+/-}$ mice have reduced numbers of GABA $_A$ receptors and display an anxiety phenotype [107, 196]. The $\gamma_2^{+/-}$ mouse spends less time in the open arms of the EPM and less time in the lit area of the light–dark box, typical of increased anxiety-type behavior. In addition, $\gamma_2^{+/-}$ mice show increased responses in the passive avoidance paradigm. This is consistent with enhanced emotional memory for negative associations, a common feature of several anxiety disorders. These behavioral alterations are associated with a lower single-channel conductance, a pronounced deficit of functional receptors, and a reduction in α_2 /gephyrin containing postsynaptic GABA $_A$ receptor clusters in cortex, hippocampus, and thalamus. Transgenic mice overexpressing either the mouse γ_{2L} or γ_{2S} subunits of the GABA $_A$ receptor showed no difference in anxiety-related behavior as compared to wild-type littermates [197]. Since compensation at the level of GABA $_A$ receptor subunit expression and assembly often occurs when subunit expression is disturbed (see below), it would be important to know the expression of all subunits in these mice. Among the α subunits, α_1 is predominant in GABA $_A$ receptors [198]. Two groups have independently generated mice with a deleted α_1 subunit and found no evidence for increased anxiety or other behavioral abnormalities [199–201]. However, an additional study demonstrated that lack of the α_1 subunit is compensated and substituted by other α subunits, presumably during development, mitigating the effect of the genetic deletion [199]. Although α_2 -subunit-deficient mice have been generated and a point mutation in this subunit (H101R) abolishes the anxiolytic effect of diazepam [202, 203], no published data exist on the behavior of these mice

except a faster habituation to a novel environment of the α_2 -subunit-deficient mice (which was interpreted as less activity in a novel environment) [204]. Therefore it is not clear if these mice have an increased anxiety phenotype. An additional complication of the interpretation of the role of the α_2 subunit can be compensation by other α subunits as occurs in the α_1 -subunit-deficient mice (see above). “Knockin” mice in the α_5 subunit (H105R) display enhanced trace fear conditioning to threat cues [196]. This is somewhat surprising because similar knockouts in the $\alpha_{1/2}$ subunits have no behavioral problems (see above). Further analysis showed that the knockin mice exhibit a 33% reduction in hippocampal (CA1 and CA3) α_5 receptor subunits; thus, these mice should be considered a partial knockout [196]. Also, α_5 receptor subunit null mutant mice exhibit improved performance in the water maze of spatial learning task but no change in locomotor activity in a novel environment [205]. Although the behavioral characterization of these mice is far from complete, it seems that the α_5 subunit is involved in hippocampal memory rather than in anxiety-related processes. Finally, the genetic inactivation of β_2 , another predominant subunit, resulted in a more than 50% reduction in the total number of GABA_A receptors and increased locomotor activity in the open field, suggesting that these receptors may control motor activity [200].

Besides the GABA_A receptor, the 5-HT_{1A} receptor has long been implicated in the pathogenesis of anxiety disorders. In 1998, three groups reported the generation of 5-HT_{1A} receptor knockout mice on different strain backgrounds [38, 206–209]. All three groups reported that the mutant mice exhibit consistently enhanced anxiety-like behaviors alongside reduced immobility in the forced-swim test [209] or tail suspension test [207, 208], indicating an antidepressant-like effect. Anxiety-related tests in these studies included open field, EPM and EZM, and novelty-induced suppression of feeding as well as fear-conditioning paradigms [207–210]. The consistency in these reports is rather remarkable because of the difference in the targeting constructs and genetic backgrounds. 5-HT_{1A} receptors are expressed both at postsynaptic locations in 5-HT target areas (such as amygdala, hippocampus, and cortex) and presynaptically on 5-HT neurons in the raphe nuclei as somatodendritic autoreceptors. Since autoreceptors control neuronal firing, it was first believed that the anxiety phenotype of the 5-HT_{1A} receptor knockout mice was the result of an increase in 5-HT release and activation of other 5-HT receptor subtypes. However, basal 5-HT levels are not altered, as measured by *in vivo* microdialysis, in 5-HT_{1A} receptor null mice [47, 211–213], and expression of 5-HT_{1A} receptors in forebrain regions rescued the phenotype of 5-HT_{1A} receptor knockout mice [214], suggesting that the behavioral phenotype results from the absence of postsynaptic 5-HT_{1A} receptors. Another interesting feature of the 5-HT_{1A} receptor knockout mice is that their anxiety-like behavior is likely the result of an irreversible early postnatal developmental abnormality [214]. In addition to increased avoidance, 5-HT_{1A} receptor knockout mice display reduced locomotor activity, another sign of increased anxiety-like behavior [214]. Another characteristic of anxiety, increased autonomic arousal (Figs. 1.2 and 1.3), was also observed in these mice. Specifically, following exposure to injection or novelty-induced stress, 5-HT_{1A} receptor knockout mice exhibited a significantly greater increase in heart rate and body temperature than wild-type mice [215, 216]. Another group reported a similar effect following footshock [37]. Taken together, 5-HT_{1A} receptor knockout mice show abnormalities in three important measures of anxiety: increased avoidance, decreased locomotor

activity, and increased autonomic arousal following exposure to a novel environment or stress. Moreover, these behavioral changes are reproducible across laboratories, which makes this genetic anxiety model not only one of the best studied but also the most robust so far in terms of the behavioral phenotype.

Another member of the 5-HT receptor family whose deletion has been associated with an alteration in anxiety levels is the 5-HT_{1B} receptor. 5-HT_{1B} receptors are predominantly localized to nerve terminals and serve as both auto- and hetero-receptors to inhibit neurotransmitter release [217, 218]. The open-field test indicated reduced anxiety-like behavior in 5-HT_{1B} receptor knockout mice [219], suggesting that this receptor may have an opposite function than that of the 5-HT_{1A} receptor (see above). Reduced anxiety was also seen in the novelty-induced suppression of feeding test [219]. However, the light–dark box and EPM tests showed no significant change in anxiety-like behavior in the 5-HT_{1B} receptor knockout mice [94, 220]. A further complication with this strain is that its behavioral phenotype was not reproducible in different laboratories even if the source of the mice was identical [220]. A similar reduced anxiety-like behavior was recently reported in 5-HT_{2A} receptor deficient mice in the EPM, open field and the light-dark box test [220a]. Importantly, the selective cortical re-expression of the 5-HT_{2A} receptor rescued the reduced anxiety-like behavior of 5-HT_{2A} receptor knockout mice indicating a role for cortical 5-HT_{2A} receptors in the modulation of conflict based anxiety-related behavior [220a].

There are two known CRH receptors (R1 and R2) and both have been suggested to be important in regulating anxiety levels. As discussed above, there are two ligands for these receptors: CRH and urocortin. Both CRH and urocortin are potent mediators of the endocrine, autonomic, behavioral, and immune responses to stress [221, 222]. CRH-R1 has a widespread distribution with high levels in anterior pituitary, hippocampus, amygdala, and cerebellum. While in the anterior pituitary CRH-R1 is involved in the activation of the HPA axis, in other regions it is responsible for the central action of CRH/urocortin and its activation is anxiogenic. In contrast to CRH-R1, expression of CRH-R2 in the CNS is restricted to the lateral septum and the ventromedial nucleus of the hypothalamus. While mice lacking CRH-R1 display decreased anxiety in the light–dark box and the EPM [223, 224], CRH-R2-deficient mice, generated independently by three groups, exhibit varying degrees of anxiety-related behavior. Bale et al. reported an increased anxiety in the EPM and open field but not in the light–dark box test in CRH-R2-deficient mice [225]. In the study of Kishimoto et al. [226], only male CRH-R2^{-/-} mice exhibited anxious behavior in the EPM and light–dark box but, paradoxically, spent more time in the center of the open field, which is more consistent with reduced anxiety. However, Coste et al. found no significant change in anxiety behavior in the EPM or open field [227]. Although not all studies are consistent with a simple interpretation, the behavioral data obtained with various CRH-R knockout mice indicate that CRH and/or urocortin mediate a dual modulation of anxiety behavior. Activation of CRH-R1 appears to be anxiogenic while activation of CRH-R2 is anxiolytic. Therefore it may not be surprising that dual CRH-R1/2 knockout mice have only a subtle behavioral phenotype; specifically, females have a reduced anxiety-like behavior in the EPM but not in the open field while males show no behavioral abnormalities related to anxiety at all [228].

As mentioned earlier, DA, presumably by regulating reward and activity, is believed to be involved in anxiety-like behavior. In particular, DA D_2 receptors have been implicated in anxiety-related behavior. Consistent with these data, DA D_3 receptor knockout mice display reduced anxiety in the open field and EPM and increased locomotor activity [229]. In contrast, D_4 knockout mice exhibit enhanced anxiety in the open-field test in the presence of a novel object [230]. While altered anxiety levels were evident, the authors interpreted much of the behavioral phenotype as changes in exploratory behavior.

Although a role for the cannabinoid 1 (CB-1) receptor is less known in anxiety-like behavior, it has been reported that CB-1 knockout mice have increased anxiety-like behavior in the light–dark box [231] and reduced exploration of the open arms of the EPM apparatus [232]. However, evidence for reduced anxiety was found in CB-1 knockout mice in the shock-probe burying test, in which anxiety is reflected by increased burying, corresponding to increased active avoidance [233].

Although the NE system and the locus ceruleus (LC) are clearly significant in the pathogenesis of anxiety as well as in animal models of anxiety, there are relatively few studies that specifically tested the role of adrenergic receptors in these conditions. So far, the α_{2a} -adrenergic receptor has been studied (among the α_{2a} , α_{2b} , and α_{2c} receptors) and mice deficient in this receptor show increased anxiety-like phenotype in various tests [234].

Consistent with the “calming” effects of adenosine and anxiety-inducing nature of caffeine, rats treated with a nonspecific antagonist at adenosine receptors [235] as well as adenosine_{2a} (A_{2a}) receptor null mice exhibit increased avoidance in the EPM and light–dark box, decreased exploratory behavior, and decreased locomotor activity (reduced activity), typical signs of increased emotionality and anxiety [236] (see also Fig. 1.3). The A_{2a} receptor is co expressed with DA D_2 receptors in GABAergic neurons in basal ganglia and striatum and is thought to regulate the expression of the proenkephalin gene [237]. In situ hybridization studies showed a decrease in proenkephalin gene expression in the A_{2a} receptor knockout mice, which may explain the anxiety-like behavior of these mice.

G-protein-gated inwardly rectifying K^+ (GIRK) channels contribute to post-synaptic inhibition triggered by many neurotransmitters, including DA and 5-HT, and GIRK2-deficient mice have been found to display a phenotype consistent with reduced anxiety [238]. Four GIRK subunits (GIRK1 to GIRK4) have been identified, and tetrameric channels formed by various combinations of GIRK1, GIRK2, and GIRK3 mediate inhibition in the nervous system [239, 240]. In addition to less avoidance in the EPM and light–dark box test, GIRK2 knockout mice also display increased locomotor activity satisfying two criteria of reduced emotionality (see Fig. 1.3).

Nicotinic agonists and antagonists can modulate anxiety [241, 242], and mice with a null mutation in the nicotinic acetylcholine receptor (nAChR) α_7 subunit gene have been shown to exhibit decreased anxiety in the open field but not in the light–dark box [243]. In contrast, mice deficient in the nAChR α_4 -subunit gene display increased anxiety in the EPM [244], indicating that the subunit composition of the nAChR may determine whether the effect is anxiogenic or anxiolytic.

One of the targets of BDNF is trkB, a receptor tyrosine kinase [245]. Consistent with the increased anxiety-like phenotype of the conditional BDNF mutant mice

[246], transgenic mice overexpressing *trkB* in postmitotic neurons in a pattern similar to that of the endogenous receptor display less anxiety in the EPM test [246].

Neurotransmitter and neuromodulator receptors are not the only substrates of communicating external signals into neurons. Cell–cell interactions are crucial in regulating neuronal functions and developmental processes. One group of proteins that mediate cell–cell interactions is represented by neuronal adhesion molecules that regulate, among others, synaptic plasticity in both the developing and adult brain. Recent studies indicate that neuronal cell adhesion molecules of the immunoglobulin superfamily (NCAM and L1) are important mediators of the effects of stress. Chronic stress alters the expression pattern of cell adhesion molecules in parallel with their effects on behavior [247]. The connection between neuronal cell adhesion molecules and emotional behavior is also supported by the change in the anxiety-like phenotype of NCAM and L1 null mice. Genetic inactivation of NCAM results in decreased anxiety in the light–dark and EPM tests [248]. In addition, these mice respond to the anxiolytic effect of buspirone in the light–dark test at lower doses than the NCAM^{+/+} mice, suggesting that there may be an alteration in the sensitivity of the 5-HT_{1A} receptors in these knockout mice. However, the authors reported no changes in the density of 5-HT_{1A} receptors or in tissue 5-HT content. Since NCAM has been demonstrated to have a role in CNS development and neuroplasticity, a developmental abnormality may explain the expression of anxiety-like behavior in these mice (similarly to the BDNF, IFN γ , and 5-HT_{1A} knockout mice; see Sections 1.9 and 1.10). Also, conditional inactivation of L1 in the forebrain, mostly from early postnatal life [by cre-recombinase under the control of the calcium/calmodulin-dependent protein kinase II (CaMK II) promoter], resulted in decreased anxiety in the open field and EPM [249]. Conditional expression avoids the severe morphological and behavioral abnormalities associated with the absence of L1 during prenatal development. Finally, the lack of cadherin-11, another cell adhesion molecule, results in reduced fear- or anxiety-related responses [250]. Cadherin-11 is expressed in the limbic system of the brain, most strongly in the hippocampus, and is densely distributed in synaptic neuropil zones. Taken together, the loss of function of three cell adhesion molecules leads to maladaptive behavioral responses that are “opposite” to anxiety and may be characterized as excessive novelty seeking and a lack of appropriate response to danger (see Fig. 1.3, blue region of the cube, and discussion in the accompanying text). It is striking that all three adhesion molecules mentioned above are involved in the regulation of synaptic structure and function [251]. This indicates that the optimal functioning of synapses is essential for mediating appropriate responses to novelty and stress.

1.11 INTRACELLULAR REGULATORS ASSOCIATED WITH ANXIETY-LIKE PHENOTYPE

A number of intracellular signaling molecules and transcription factors have been shown to cause increased or reduced anxiety-like phenotype in mice. The α isoform of CaMKII is an important second messenger, and Chen et al. [252] demonstrated decreased anxiety in CaMKII knockout mice. CaMKII is a major component of the postsynaptic density in glutamatergic synapses [253] and is involved in neuronal

functions related to calcium signaling, including the induction of long-term potentiation (LTP) [254]. Therefore, the disruption of CaMKII function could alter many aspects of neuronal function, making it difficult to relate it to a specific anxiety behavior. Indeed these knockout mice also exhibit enhanced aggression and learning impairment.

The serine/threonine kinase protein kinase C γ (PKC γ) has recently been shown to be a regulator of anxiety behaviors [255]. PKC γ is restricted to the CNS and is highly expressed in limbic areas of the brain. In three different behavioral tests (EPM, light–dark test, mirrored chamber) PKC γ knockout mice consistently showed reduced anxiety-like behavior. Bowers et al. [255] proposed that PKC γ modulates anxiety by altering the function of GABA_A, *N*-methyl-D-aspartate (NMDA), or 5-HT₂ receptors.

Another intracellular signaling molecule implicated in anxiety and fear responses is the tyrosine kinase Fyn. Fyn is a member of the Src family of tyrosine kinases that can associate with and phosphorylate a variety of molecules. Inactivation of the *fyn* gene in mice results in increased anxiety-like behavior to naturally aversive stimuli in the light–dark box and novelty tests [256]. These mice also display enhanced learned fear responses in the passive-avoidance test. Fyn is highly expressed in the limbic system and has been implicated in NMDA receptor-mediated synaptic plasticity, NCAM-dependent neurite outgrowth, and myelination [257–259]. Whether any or all of these processes are involved in the enhanced anxiety exhibited in the Fyn^{−/−} mice is unclear.

The NF- κ B transcription factor family is linked to a number of receptors, including TNF α , and controls the expression of many genes involved in cell survival, proliferation, and regulation of inflammatory and stress responses. It has recently been shown that mice lacking the p50 subunit of NF- κ B have a reduced anxiety-like phenotype [260]. These mutant mice showed reduced avoidance and autonomic arousal in the open field and EPM. In immune cells, NF- κ B factors are kept inactive by association with inhibitory proteins belonging to the I κ B family and activating stimuli induce the phosphorylation, polyubiquitination, and proteasome degradation of I κ Bs, allowing NF- κ B to translocate into the nucleus and activate target genes. In contrast, it seems that either NF- κ B is constitutively active in neurons [261] or normal neuronal activity is sufficient to keep a substantial amount of NF- κ B in an active form. Since it is expressed during development [262], NF- κ B may regulate the development of brain circuits, and consequently the reduced anxiety-like phenotype of p50 knockout mice could be due to abnormal brain development.

GR is another transcription factor (activated via the HPA axis and glucocorticoid hormones) and is well known to be involved in stress response and some anxiety disorders. As discussed later, a brief period of controllable stress experienced with general arousal and excitement can be beneficial, but chronically elevated levels of circulating corticosteroids are believed to enhance vulnerability to a variety of diseases, including affective disorders. Therefore it is not surprising that the genetic manipulation of GR results in changes in emotionality in mice. Reduced anxiety-like phenotype was found in a brain-specific GR knockout [263] and in a GR-antisense model with reduced GR expression in brain and some peripheral tissues [264], while GR overexpression in forebrain results in increased anxiety-like behavior [265]. Together, these findings indicate that a sustained increase in GR activity in brain is associated with increased anxiety-like behavior.

In addition to its role in the regulation of calcium and phosphate homeostasis and in bone formation, vitamin D is also thought to be involved in brain function. Genetic ablation of the vitamin D receptor (VDR), another nuclear receptor linked to transcription, results in increased anxiety-like behavior in a battery of behavioral tests [266].

Still another group of transcription factors associated with anxiety-like behavior is the family of cyclic adenosine monophosphate (cAMP)-responsive nuclear factors that consist of CREB, CRE modulator (CREM), and activating transcription factor 1 (ATF-1) [267]. A conditional CREB mutation that inactivates all isoforms in the brain or the disruption of the two major transcriptionally active CREB isoforms (α and δ) increases anxiety-like responses in mice in different behavioral tests, including the EPM [268]. In CREB-deficient mice, the expression of CREM isoforms is increased [269]; thus, the higher anxiety-like phenotype may be attributable to this change. Indeed, CREM-deficient mice display reduced anxiety-like behavior in the EPM test and also exhibit hyperactivity [270], indicating that CREM activity may be linked to neuronal modulation promoting anxiety.

BC1 RNA is a small non-messenger RNA common in dendritic microdomains of neurons in rodents, and it is believed to play a role in translational regulation. Mice mutant for BC1 show behavioral changes consistent with increased anxiety and reduced exploration [271]. These data indicate that an anxiety-like phenotype can be induced by disturbing gene expression beyond transcription at the translational level.

Taken together, defects in intracellular processes involving second messengers, transcription factors, and translational factors can lead to alterations in anxiety in mice. To better understand the neurobiology of anxiety, it will be critical to identify the specific mRNAs and proteins whose altered synthesis in neurons of the fear/anxiety pathway is associated with the expression of the behavioral phenotype. In any event, the common feature of these molecular changes is that they could all eventually influence morphological and/or functional plasticity in the nervous system (see further discussion on this topic below).

1.11.1 Modeling Complex Genetics of Anxiety in Mice: Oligogenic Anxiety-Like Conditions in Mice

Genetic studies on various mouse phenotypes clearly indicate that most behavioral traits are heritable and are specified by multiple genes or QTLs. For example, mapping studies have estimated that the individual anxiety-related behavioral differences in the DeFries recombinant inbred strains of mice are the result of the interaction between four to six QTLs for each behavior; the largest QTL explains no more than half of the variance attributable to the detected QTL [15, 272, 273]. However, QTLs can consist of hundreds of genes, and these studies are not designed to analyze the contribution of individual genes to anxiety. An alternative strategy to study the combined effect of two or more genes on behavior is to use double- and triple-knockout mice. A recent report analyzed anxiety-related behaviors in double 5-HTT^{-/-} and BDNF^{+/-} mutant mice [274]. These mice, as compared to 5-HTT^{-/-}, BDNF^{+/-}, and wild-type mice, displayed a significantly higher level of anxiety-like behavior, reduced levels of 5-HT and 5-hydroxyindole acetic acid in the hippocampus and hypothalamus, and greater increases in plasma ACTH after a

stressful stimulus. These findings support the hypothesis that genetic changes in BDNF expression interact with 5-HT to modulate anxiety and stress-related behaviors.

Another double-knockout strain lacking both monoamine oxidase (MAO) A and B, two enzymes responsible for the degradation of monoamines, shows anxiety-like behavior in various tests [275]. Neither the MAO_A nor the MAO_B knockout mutants display anxiety in these tests, indicating that an interaction between the two MAO genes leads to a novel phenotype [276, 277]. Since monoamine levels are higher in the double knockouts than in the single mutants, the abnormal behavior of MAO_{A/B} mutants is likely the consequence of altered monoaminergic neurotransmission.

1.12 EFFECTS OF EARLY-LIFE ENVIRONMENT ON ANXIETY

1.12.1 Early-Life Experience on Expression of Anxiety in Later Life

A large body of evidence supports the notion that early-life environmental effects alter life-long stress-coping mechanisms. Unlike human studies, which are predominantly retrospective with a large number of environmental variables, animal research has focused on the effect of “handling” and maternal care during postnatal development. Brief handling of pups results in life-long decreases in behavioral and endocrine responses to stress while animals separated from their mothers/litters for longer periods of time (i.e., for several hours) exhibit increased anxiety [278–280]. Later studies determined that the critical feature of short-term handling was the increase in maternal care [licking and grooming (LG)] following the return of pups [281]. Variability in maternal care can produce large differences in adult behavior and hormonal responsiveness to stress. Pups nursed by mothers with either a high or a low level of LG and arched-back nursing (ABN) show a decreased and increased level of anxiety-like behavior in adult life (open field, novelty-suppressed feeding, and shock-probe burying assays), respectively [281–284]. Also, offspring of high LG–ABN mothers (as well as briefly handled pups) have reduced plasma levels of ACTH and corticosterone in adulthood following stressful stimuli such as restraint stress when compared to the offspring of low LG–ABN mothers (or nonhandled pups) [285]. Furthermore, these animals show increased glucocorticoid feedback sensitivity, increased hippocampal GR mRNA expression, and decreased hypothalamic CRH mRNA levels.

Interestingly, pups born to low LG–ABN mothers but cross fostered to high LG–ABN mothers develop low anxiety-like behaviors in adulthood, but high LG–ABN pups reared by low LG–ABN mothers do not develop increased anxiety-like responses in adulthood [285]. Furthermore, the maternal behavior of female offspring from low LG–ABN mothers can be changed by cross fostering them to high LG–ABN mothers. The reverse, however, is not true because daughters of high LG–ABN mothers raised by low LG–ABN dams have high LG–ABN maternal behavior [281, 286]. Finally, offspring of low LG–ABN mothers, if cross fostered to high LG–ABN mothers, show hormonal levels similar to those observed for offspring of high LG–ABN mothers [285]. These findings suggest that environmental effects may overpower genetic predispositions, particularly in cases where such modification would be beneficial for survival.

Although experiments related to both postnatal handling and maternal behavior clearly show a nongenomic influence on anxiety-like behavior, the transmission

mechanism of this effect has been difficult to elucidate. It has been hypothesized that environmental influences exert some level of control on the development of HPA and the regulation of HPA function via a number of neurotransmitter systems, including the noradrenergic, GABAergic, and glutamatergic systems [287, 288]. For example, rat pups of high LG-ABN dams show altered GABA_A receptor subunit expression in the amygdala, LC, medial prefrontal cortex, and hippocampus that could contribute to their reduced anxiety-like behavior as compared to pups from low LG-ABN dams [289, 290]. In addition to the GABAergic system, other potential factors mediating the environmental effects include the glutamatergic system and neurotrophins such as BDNF. Liu et al. [291] found that adult offspring of high LG-ABN Long Evans dams show increased hippocampal synaptogenesis and better spatial learning and memory than low LG-ABN offspring and that these differences could be equalized if low LG-ABN pups were cross fostered to high LG-ABN dams. More specifically, increased LG-ABN of offspring resulted in increased hippocampal mRNA expression of NR2A and NR2B NMDA receptor subunits at postnatal day 8, a change that was sustained into adulthood. Consistent with the regulation of the BDNF gene by NMDA receptors [292], increased levels of BDNF, but not NGF or NT-3, mRNA were observed in the dorsal hippocampus of eight-day-old high LG-ABN pups [291]. Most recently, it has been reported that the maternal effect is linked to alterations in methylation and chromatin structure at the GR promoter in the offspring [291a]. It has been proposed that downregulation of hippocampal GR in the pups of low nursing mothers compromises feedback inhibition in the hypothalamic pituitary adrenal axis ultimately leading to higher anxiety states [291a]. Since GR knockout mice have reduced anxiety [263] and GR overexpression in forebrain results in increased anxiety-like behavior [265], it is possible that the maternally-induced regulation is specific for a subset of GRs and does not involve the GR pool implicated in the stress related actions of glucocorticoids.

1.12.2 Interaction of Environment with Genes in Establishing Level of Anxiety

Although the interaction of genes and environment in shaping personality is well accepted, direct experimental evidence to support this notion has been difficult to obtain in humans. Recent association studies, however, have clearly indicated that genetic and environmental factors act together, enhancing the phenotype beyond the level established by either factor alone. For example, promoter polymorphism in 5-HTT can influence anxiety-related behavior (*s/s* genotype represents a predisposition to neuroticism/anxiety) [9], and a recent report showed that this polymorphism moderates the influence of stressful life events on depression. Individuals with one or two copies of the *s* allele of the 5-HTT promoter polymorphism exhibited more depressive symptoms in relation to stressful life events than *l/s* individuals [293]. Although this study was focused on depression, anxiety is a common symptom in depression, and future studies may reveal evidence of an interaction between an individual's 5-HTT allelic makeup and environmental insults in anxiety disorders. This connection has already been made in primates. Rhesus monkeys have a 5-HTT polymorphism similar to that found in humans, and it was shown that although both mother-reared and nursery-reared heterozygote (*l/s*) animals demonstrate increased affective responding (a measure of temperament) relative to *l/l* homozygotes,

nursery-reared but not mother-reared *l/s* infants exhibited lower orientation scores than their *l/l* counterparts [294]. Also, monkeys with deleterious early rearing experiences were differentiated by genotype in cerebrospinal fluid concentrations of the 5-HT metabolite, 5-hydroxyindoleacetic acid, while monkeys reared normally were not [295]. Another study found that separation-induced increases in ACTH levels were modulated by both rearing condition and 5-HTT polymorphism [296]. During separation, animals with *l/s* genotypes had higher ACTH levels than *l/l* animals, and peer-reared *l/s* animals had higher ACTH levels than all other groups, including mother-reared animals.

Rodents are more amenable to such studies, and there have been a number of reports on the effect of early-life experience and gene interaction on later-life behavior. For example, early-life handling or cross fostering of highly neophobic BALB/c mice to less neophobic C57BL/6 mice equalizes both the behavioral and the benzodiazepine receptor expression differences between these two strains as well as decreasing the ACTH release following an acute stressor of BALB/c mice in adulthood [284, 297–299]. Furthermore, the effect of the 5HT_{1A} receptor gene on the anxiety-like behavior may be modulated by the environment. In a recent study, Weller et al. documented that F1 5HT_{1A}R^{+/-} offspring reared by 5HT_{1A}R^{-/-} mothers have increased ultrasonic vocalization (USV) when compared to F1 5HT_{1A}R^{+/-} offspring raised by 5HT_{1A}R^{+/+} dams [300]. However, contrary to expectations, F1 5HT_{1A}R^{+/-} offspring reared by 5HT_{1A}R^{-/-} mothers have decreased measures of anxiety in the EPM as adults when compared to F1 5HT_{1A}R^{+/-} offspring raised by 5HT_{1A}R^{+/+} dams. Also, 5HT_{1A}R^{-/-} pups reared by either 5HT_{1A}R^{-/-} or 5HT_{1A}R^{+/-} dams produced less isolation-induced response (USV) than their 5HT_{1A}R^{+/+} controls [300]. Although it is difficult to consolidate these seemingly contradictory results, these experiments show that the level of anxiety associated with 5HT_{1A}R deficiency can be altered by environmental factors.

In addition to early environmental influences, later-life or adult environment can also influence the expression of emotionality, as demonstrated in mouse models. As discussed previously, lack of the nociceptin/orphanin FQ gene leads to an enhanced anxiety phenotype in mice [184, 185]. The strength of the behavioral expression of the phenotype is dependent, however, on environmental influences such as social interactions. Ouagazzal et al. found that homozygous mutant animals, when housed alone, performed similarly to their wild-type controls on tests of emotional reactivity. Enhanced emotionality became apparent only when the singly housed animals were introduced to group housing (five animals per cage) that induced greater levels of aggression and increased anxiety responses [301].

Taken together, these data show that both genetic and environmental factors have an important role in establishing emotionality in mammals. Often, these factors work together, enhancing the phenotype beyond the level established by either factor alone. Other times, the environmental influences can partially or fully rescue undesirable phenotypes caused by genetic predispositions or mutations, enhancing the likelihood of the organism's survival.

1.13 CONCLUSIONS: NEUROBIOLOGY OF ANXIETY DISORDERS

Combining what is known about anxiety disorders (including symptomatology, pharmacology, and biochemistry) with the genetic and molecular information

gathered from the diverse knockout mouse strains that exhibit alterations in anxiety-like behavior, it becomes apparent that anxiety-related pathways and processes involve communication between neurons (including neuronal messengers and their receptors) and/or signaling within cells (Fig. 1.6 [302]). Since the manipulation of a ligand, its receptor, and a coupled intracellular signaling elicits a similar anxiety-like behavior, it is possible to cluster these molecules to pathways. Many of these pathways eventually converge onto regulation of transcription and/or translation, and one can hypothesize that anxiety-like behavior is the result of changes, at least in part, at the level of gene expression (Fig. 1.6). Indeed, the genetic manipulation of transcription (by CREB, GR, VDR, and NF- κ B; see previous sections) can also result in changes in anxiety levels.

Several of these “anxiety-related pathways” can be established. For example, the “serotonergic” pathway consists of receptors controlling the release of 5-HT (5-HT_{1A} and 5-HT_{1B} receptors), 5-HTT, postsynaptic 5-HT receptors, and mitogen-activated protein kinase/extracellular regulated protein kinase (MAPK/ERK) signaling (Fig. 1.6). As described in this chapter, a change in any of these components can lead to altered emotional behavior. The proper function of this pathway is especially crucial during early postnatal development, and one can hypothesize that abnormal signaling via this system alters the development of neuronal networks and consequently function, manifested as abnormal fear/anxiety response. BDNF, whose deficiency has also been associated with anxiety-like behavior, is also linked to the MAPK–ERK signaling (Fig. 1.6), suggesting that the two distinct anxiety-associated traits (deficit in 5-HT_{1A} and BDNF) may share downstream targets. In addition to the convergence of various pathways, the same extracellular signal can diverge to various intracellular pathways illustrated by the coupling of the 5-HT_{1A} receptor to both the MAPK–ERK and NF- κ B pathways [303–307] (Fig. 1.6). Such divergence obviously broadens the clusters of affected genes. Since manipulation of the p50 subunit of NF- κ B (activated by cytokines) can also be linked to anxiety-like behavior, crosstalk is extensive at the signaling level and therefore within and between anxiety-related pathways. Although the function of 5-HT and BDNF pathways is altered not only as a result of mutations and genetic polymorphisms but also by the environment, another “anxiety-related” pathway consisting of CRH, ACTH, and GR is especially sensitive to environmental changes. As with the other pathways, activation of this pathway by chronic stress eventually alters gene regulation (via GR).

It is hypothesized that abnormalities in these pathways at any level lead to, via altered gene expression, changes in neuronal morphology and/or function. Indeed, a number of knockout mouse strains with an anxiety-like phenotype as well as rodents following chronic stress show altered dendritic arborization in hippocampus and amygdala [308, 309], abnormal synapse formation [126, 250, 310], and altered electrical properties of neurons [311]. These changes result in abnormal neuronal network activity characterized by a deficit in short-term plasticity (i.e., hippocampal paired pulse facilitation and inhibition) [210, 312, 313], abnormalities in long-term potentiation [250, 312], an increase in network excitability [210, 311, 314], and abnormal activation or inhibition of brain regions as measured by fMRI [74, 75, 78]. In anxiety disorders, multiple molecular pathways may be simultaneously affected in multiple brain regions, consistent with the multitude of associated symptoms. Importantly, all commonly used anxiolytic drugs [benzodiazepines, selective

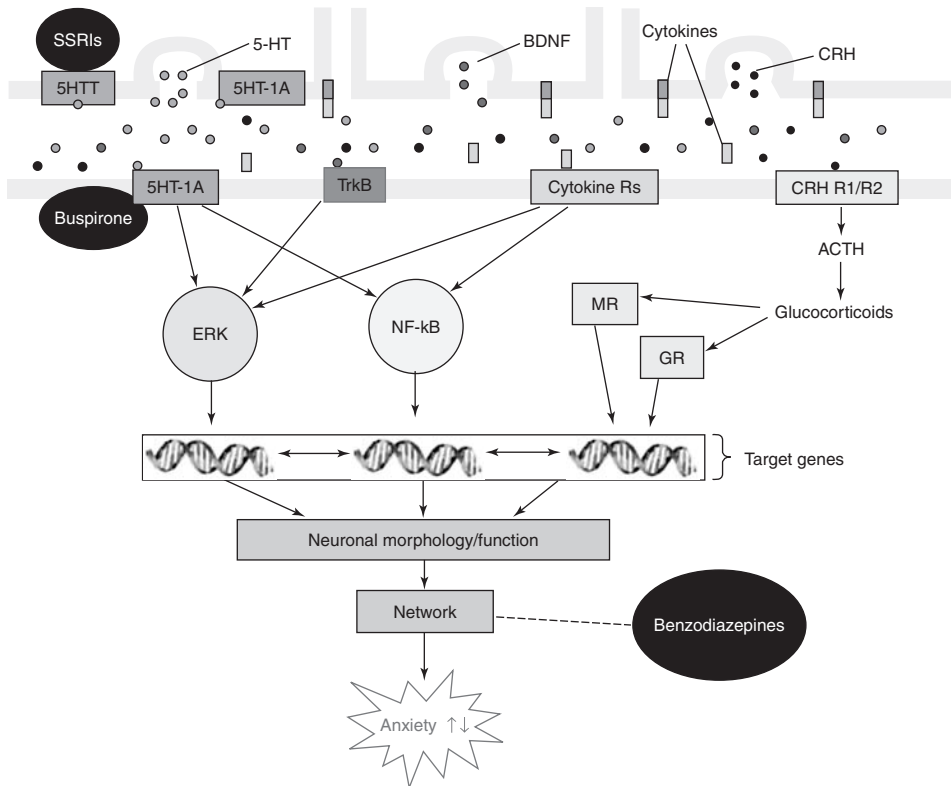

Figure 1.6 Unifying model of pathogenesis of anxiety. Pharmacological and genetic studies indicate that defects in specific substrates of neuronal communication (e.g., 5-HT, GABA, 5-HT receptors), intracellular signaling (e.g., ERK), and gene expression (GR) may be involved in anxiety-related behavior. These extracellular neuronal messengers and their associated receptors and coupled intracellular signaling form specific pathways. Abnormalities in these molecular pathways at various levels can directly modify the function/morphology of the neuronal network associated with fear, ultimately producing changes in anxiety levels. (See color insert.)

serotonin reuptake inhibitors (SSRIs), and buspirone] can be integrated into the model described above, indicating that the genetic data are consistent with the pharmacological data and that anxiolytic drugs target and modulate the molecular and cellular pathways which apparently control or establish (during development) the level of anxiety (Fig. 1.6).

2.1 INTRODUCTION

The medical treatment of anxiety disorders is passing through an interesting phase. The range of therapeutic options is expanding and public interest in the field is high. Longstanding controversies, such as the relative merits of psychological therapies versus medication and the safety of medical treatments of anxiety, are debated in the national media. Patients are increasingly active participants in the therapeutic process using widely available sources of medical information, while government guidelines seek to standardize prescribing practice and have provoked debate within the medical profession. The management of anxiety continues to sit uncomfortably between primary and secondary care and in many ways remains the poor relation within mental health care in most if not all countries. Nevertheless current medical practice is based on a substantial volume of research evidence and clinical experience, and it is possible to justify with confidence the treatment options put before patients.

The diagnostic concept of anxiety has undergone progressive evolution since Donald Klein described the discrimination of panic disorder from other neuroses [1]. New diagnostic categories have emerged, and although some discrepancies remain between different classifications, general agreement has been reached for the diagnostic validity of the main categories. This has allowed quantitative measurement of the prevalence and economic burden of anxiety disorders in epidemiological surveys [2, 3], and this evidence has been a key factor driving research into anxiolytic therapies.

The rapid advances of the past 15 years have also been driven by developments in a diversity of other disciplines, including preclinical and clinical pharmacology, cognitive and experimental psychology, and neuroscience (particularly neuroimaging). Research from areas such as genetics and molecular biology is only just beginning to have an impact. This chapter describes the current basis of pharmacotherapy for anxiety disorders, but with the pace of scientific discovery this is a field that is likely to undergo further change in the years ahead.

2.2 CLINICAL MANAGEMENT OF ANXIETY

Management of an anxious patient involves far more than the prescription of medication (Fig. 2.1). Establishing the diagnosis of a specific anxiety disorder is a critical part of the assessment process that may greatly influence the treatment offered. Anxiety disorders frequently present with comorbid conditions such as depression, alcohol or substance use problems, and other anxiety disorders, which must be detected and managed appropriately. A patient tends to present when anxiety causes impairment of their social, occupational, or domestic functioning, and identification of the key complaints helps in drawing up an effective management plan; for example, a patient with generalized anxiety disorder may complain that insomnia impairs his or her ability to work, and management should include strategies to improve sleep efficiency as well as treatment of the anxiety. Most anxiety disorders and any concomitant depression are associated with an increased risk of suicidal thoughts and acts of deliberate self-harm, and these should be carefully assessed and monitored during treatment.

Psychoeducation helps engagement and improves recovery. Models of anxiety disorders have been described in both the biological and psychological dimensions,

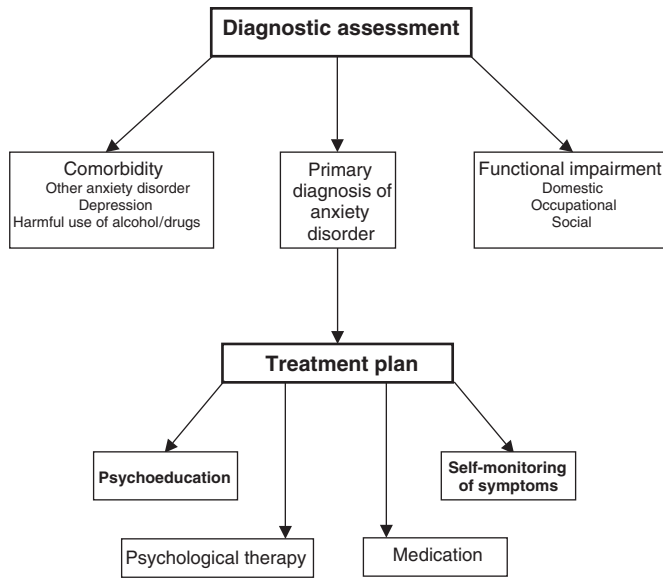

Figure 2.1 Clinical assessment of anxious patient.

and patients benefit from an explanation, tailored to their level of understanding, in each dimension. This can be reinforced by the use of educative literature [4]. Treatment efficacy is improved when patients monitor and record their symptoms [5].

A management plan is negotiated with the patient by considering any appropriate biological and psychological treatments. A combination of drug and psychological therapies can be more effective than either alone [6]. The patient may have preconceptions about specific therapies, often as a result of their anxiety; for example, a patient with panic disorder fears the effects of drugs and a patient with social anxiety baulks at the suggestion of group therapy. An open discussion of benefits and adverse effects, including long-term side effects, is likely to improve compliance. Although medications are generally well tolerated, some side effects commonly occur, and anxious patients tend to experience more than others [7]. Progress with treatment should be encouraged by regular review, particularly in the early stages.

2.3 DIAGNOSIS OF ANXIETY DISORDERS

Although every method for categorizing anxiety disorders has its shortcomings, in current clinical practice the diagnostic criteria of the American Psychiatric Association [fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)] is most commonly used [8]. *Anxiety disorder* is divided into syndromes with clear operational criteria. In particular, the criteria are clearly stated for a symptomatic individual to become a case, and this diagnostic threshold is defined either by the level of distress experienced by the individual or in terms of impairment of occupational, social, or domestic functioning. Patients may have symptoms from more than one diagnostic category, but it is important to elicit the primary diagnosis, as this will influence the recommended treatment. Comorbid disorders, usually a

TABLE 2.1 Diagnostic Criteria for Major Anxiety Disorders

Generalized anxiety disorder (GAD)	Excessive worry/anxiety about various matters for at least 6 months; difficulty in controlling worry; accompanying somatic symptoms (effects of chronic tension); clinically important distress or impairment of functioning
Obsessive-compulsive disorder (OCD)	Presence of obsessions (thoughts) or compulsions (behaviors); symptoms felt by patient to be unreasonable or excessive; clinically important distress or impairment of functioning
Panic disorder with/without agoraphobia ^a	Severe fear or discomfort peaking within 10 min; characteristic physical/psychological symptoms; episodes are recurrent and some unexpected; anxiety about further attacks or consequences of attacks
Post-traumatic stress disorder (PTSD)	Severe traumatic event that threatened death or serious harm; felt intense fear, horror, or helplessness; repeated reliving experiences; phobic avoidance of trauma-related stimuli; hyperarousal; symptoms lasting > 1 month and causing clinically important distress or impairment of functioning
Social anxiety disorder	Recurrent fears of social or performance situations; situations avoided or endured with distress; clinically important distress or impairment of functioning
Specific phobia	Persistent fear/avoidance of specific object or situation; phobic stimulus immediately provoking anxiety response; clinically important distress or impairment of functioning.

Source: After DSM-IV.

^aAgoraphobia: anxiety about place/situation where panic attack is distressing or escape difficult; situation is avoided, endured with distress or companion is required.

second anxiety disorder, mood disorder, or substance use disorder, are common and must be detected. The key diagnostic criteria for the major anxiety disorders are given in Table 2.1.

2.4 ANXIOLYTIC DRUGS

The use of substances for their anxiolytic properties dates from the beginning of recorded human history. The last century saw the development of their use for medical purposes, and major progress was made in the 1990s, “the decade of anxiety,” as advances in neuroscience provided a basis for the design of new treatments. There are now drugs available that are better tolerated, although not necessarily more effective, than their predecessors. Despite growing knowledge of the complex neural pathways involved in anxiety, it is notable that the actions of current drugs occur via a small number of neurotransmitter systems, with the most important being the monoaminergic neurotransmitters [serotonin (5-HT), noradrenaline, and to a lesser extent dopamine] and the amino acid neurotransmitters [chiefly γ -aminobutyric acid (GABA) but also glutamate].

2.4.1 Drugs Acting via Monoamine Neurotransmission

Interest in this field originated with the serendipitous discovery of the tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs), when these drugs were later found to exert their anxiolytic effects via actions on monoamine systems. Recent research, rather than clarifying the role of these neurotransmitters in anxiety pathways, has tended to present an increasingly complex picture [9]. Nevertheless these advances have led to the development of “designer drugs” with selective effects on serotonergic and noradrenergic neurones. Drugs such as the selective serotonin reuptake inhibitors (SSRIs) do not exceed their predecessors in terms of anxiolytic efficacy [10], but improved tolerability has led to their adoption as first-line treatments for anxiety disorders. The historical development of drugs in this field is illustrated in Fig. 2.2.

The monoamines are relatively simple molecules that are synthesized within neurons from dietary amino acids. They facilitate transmission in neural pathways that originate in brain stem nuclei and have descending projections to the autonomic nervous system and widespread ascending projections to sites in the limbic system and cortex. In addition to the control of anxiety responses, these pathways modulate many other aspects of behavioral function, including mood, appetite, and sleep.

Among the monoamines the role of 5-HT in anxiety is best understood, but the picture is complex as increased serotonergic activity may be anxiogenic or anxiolytic depending on the site and duration of action [11]. 5-HT is released into the synapse and either binds to postsynaptic receptors or reenters the neuron via a specific transporter (Fig. 2.3). The serotonergic neuron regulates its own firing rate via the action of inhibitory autoreceptors. Anxiety disorders have been shown to be associated with various alterations in the serotonergic neuron including reduced

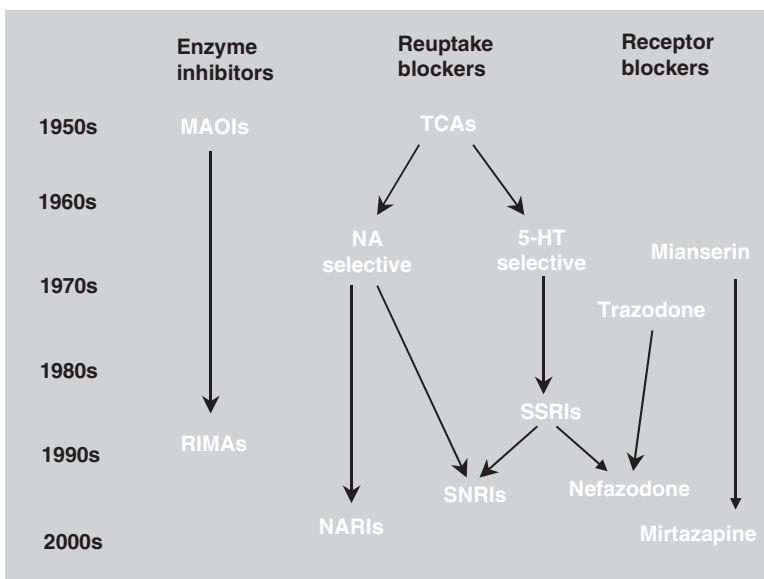

Figure 2.2 Historical development of antidepressant drugs.

Figure 2.3 Actions of anxiolytic drugs on serotonergic neurone.

binding to presynaptic and postsynaptic 5-HT_{1A} receptors [12] and possibly with a genetic variation in the 5-HT transporter [13].

Anxiolytic drugs can alter monoaminergic neurotransmission by increasing synaptic availability or by direct action on postsynaptic receptors. Mechanisms for increasing monoamine availability include promoting release by blocking inhibitory autoreceptors, decreasing reuptake by blocking transporters, and decreasing metabolism by inhibiting oxidative enzymes. Monoamines are also implicated in the pathophysiology of depression, and drugs that increase their synaptic availability tend to have antidepressant effects. These drugs have been traditionally classified as antidepressants, although they have a primary role as anxiolytics and are currently the major drug class in the field. Other anxiolytic drugs acting via monoamines are the postsynaptic serotonin receptor partial agonist buspirone, the β -adrenoceptor blockers, and drugs classed as antipsychotics, which are primarily antagonists at postsynaptic monoamine receptors.

2.4.1.1 Antidepressants. Taken together the efficacy of antidepressants covers the spectrum of anxiety disorders, although there are important differences between drugs in the group (Table 2.2). Several new antidepressants have been marketed since the SSRIs: venlafaxine and mirtazapine are discussed later; nefazodone, a serotonin reuptake inhibitor and postsynaptic 5-HT₂ blocker, showed promise in early studies but was recently withdrawn by its manufacturers; and reboxetine, a noradrenaline reuptake inhibitor (NARI), showed benefits in panic disorder in one published study [14] and further evidence of its anxiolytic efficacy is awaited.

There are important differences between antidepressants and other drug groups in the onset and course of their actions (Fig. 2.4). There is often an increase in anxiety on initiation of therapy, and anxiolytic effects occur later. In comparative studies improvement matches that on benzodiazepines after four weeks [15]. Withdrawal effects, particularly rebound anxiety, are less problematic with antidepressants than with benzodiazepines, although stopping treatment is associated with a significant

TABLE 2.2 The Use of Antidepressants in Anxiety Disorders

Parameter	SSRI/SNRI ^a	TCA	Mirtazapine	MAOI/RIMA ^b
Efficacy	GAD, OCD, panic disorder PTSD, social anxiety disorder	Panic disorder, OCD (GAD, PTSD)	Panic disorder, PTSD	Panic disorder, PTSD, social anxiety disorder
Tolerability	Onset worsening, side effects on initiation, few long-term effects	Onset worsening, side effects on initiation, some long-term effects	Few side effects on initiation, few long- term side effects	Significant short- and long- term side effects, special dietary requirements, moclobemide better tolerated
Safety	Relatively safe in overdose	Significant overdose toxicity	Relatively safe in overdose	Significant overdose toxicity (less with moclobemide)
Discontinuation syndrome	Well-described, more common with paroxetine and venlafaxine, uncommon with fluoxetine	Well described	Not reported	Reported

risk of relapse and a withdrawal (discontinuation) syndrome has been described for most of the antidepressants with short half-lives.

2.4.1.1.1 SSRIs. These drugs increase the availability of synaptic 5-HT by selectively blocking the 5-HT reuptake transporter (Fig. 2.3). In preclinical and human studies acute doses are anxiogenic [16] but chronic administration has anxiolytic effects, possibly due to downregulation of presynaptic autoreceptors [17]. There are five SSRIs widely available: citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. Escitalopram, the S enantiomer of citalopram, has been demonstrated to be effective in several studies of anxiety disorders and has the same spectrum of efficacy as citalopram [18]. The SSRIs as a class are now widely considered to be appropriate first-line anxiolytic drugs; in particular, paroxetine, one of the most potent 5-HT reuptake blockers, has been licensed in the United Kingdom for the treatment of each of the major anxiety disorders. Efficacy has been clearly demonstrated for SSRIs in randomized controlled trials of up to six months, but in common with other antidepressants research evidence is lacking for longer term efficacy.

A major advantage of the SSRIs is their improved tolerability relative to the TCAs and benzodiazepines, which has been demonstrated in comparisons of drugs from these classes [19, 20]. Nevertheless they are not without side effects: On initiation nausea, anxiety, jitteriness, and insomnia are related to the starting dose; later sedation, asthenia, headache, sweating, and sexual dysfunction may occur. Hyponatremia is a problem most likely to be seen in the elderly. Some effects are particular to individual drugs within the class [21]. For example, paroxetine has some anticholinergic properties and can cause dry mouth, constipation, and urinary hesitancy; sertraline is more likely to cause dyspepsia and diarrhea; and fluoxetine has agonist activity at 5-HT_{2C} receptors, causing headache, agitation, and loss of appetite, possibly explaining its efficacy in bulimia [22].

Although SSRI overdose can cause seizures, coma, and cardiac abnormalities [23], these toxic effects occur only in large overdoses or in combination with other drugs. Fatality rates are very substantially lower than with TCA overdose [24, 25]. Public attention has been drawn to reports of suicidal and aggressive thoughts and behavior associated with SSRI therapy [26]. The scientific basis for this assertion is disputed, and a number of conflicting factors have been considered [27, 28]. Both anxiety disorders and related depression significantly increase the risk of suicide and successful treatment

reduces this risk. However, there are periods within treatment when clinical factors can lead to an increased risk; for example, as energy levels improve, the patient may be more likely to act upon existing suicidal thoughts, and this phenomenon was observed before the advent of antidepressants. Furthermore there may be factors specific to antidepressant therapy that cause increased suicidality, such as side effects of agitation, restlessness, and increased anxiety which are possibly due to activation of postsynaptic 5-HT₂ receptors by increased synaptic 5-HT. These factors have been particularly highlighted as relating to the use of SSRIs but are in reality common to most antidepressants. The assessment and monitoring of suicidality are an integral part of the clinical management of any patient with anxiety or depression. It is debatable whether SSRI therapy presents a special risk in this area, and taking a broader view it appears that SSRI treatment is associated with reduced suicidality on a population level [29, 30].

A further controversy that has surfaced in the lay media is the misleading claim that SSRIs have “addictive” properties. This centers around reports of patients suffering symptoms when trying to discontinue medication. In many cases these symptoms are a recurrence of the original anxiety disorder, often as a result of suboptimal treatment, although an important difference between antidepressants and benzodiazepines is that rebound anxiety (a rapid return of the original symptoms) has not been clearly demonstrated with antidepressants. There is also a well-described transient discontinuation syndrome associated with SSRI withdrawal, that is, a reaction occurring as brain levels of the drug are falling that is not a feature of the underlying disorder [28, 31]. The most frequently occurring symptoms are dizziness, nausea, and headache (Table 2.3), with a typical duration of two to four days. The syndrome is most common with paroxetine, possibly due to its anticholinergic activity, and is very uncommon with fluoxetine due to the long half-life of its metabolites [32]. Although prominently highlighted with SSRIs, a similar syndrome has been observed with most, although not all, antidepressants. It can start as soon as 48 h after the final dose, and although most cases resolve within two to three weeks, symptoms may rarely last longer than this. Difficult cases can be managed by reinstituting the drug and withdrawing slowly, if necessary using liquid preparations, or by switching to a drug with a long half-life such as fluoxetine. Patients should be counseled about possible withdrawal problems at the start of therapy, although with careful management significant problems should not be common.

TABLE 2.3 SSRI Discontinuation Syndrome

Symptoms	Neurological symptoms: dizziness, tremor, vertigo, paraesthesia/shooting pains Psychological symptoms: anxiety, confusion, memory problems Somatic distress: nausea, headache, lethargy Hyperarousal: agitation, restlessness, insomnia, irritability
Risk factors	Treatment factors: longer duration of treatment, rapid discontinuation, short half-life drug, possibly increased dose Patient factors: possibly younger age, any psychiatric diagnosis
Therapeutic strategies	Careful assessment, reassurance, reinstitute therapy if necessary, taper slowly (over 1 month), switch to fluoxetine

SSRIs may interact with other drugs that have effects on 5-HT neurotransmission, including TCAs, buspirone, sumatriptan, and tryptophan, but particularly important is the interaction with MAOIs that can lead to a synergistic increase in synaptic 5-HT. This can result in the potentially lethal “serotonin syndrome,” comprising restlessness, irritability, tremor, sweating, and hyperreflexia [33]. In clinical practice there should be a washout of two weeks between discontinuing MAOI therapy and starting SSRI; a washout of one to two weeks should follow SSRI discontinuation (five weeks for fluoxetine). The drugs have variable potential for drug interactions via hepatic cytochrome P450 enzymes (Table 2.4). Citalopram and escitalopram have the lowest potential for interactions.

Expert sources and government guidelines recommend SSRIs as first-line drug treatments of anxiety disorders [34–37]. In preparation for treatment a full discussion of potential benefits and anticipated side effects (including discontinuation effects) should be held with the patient [38]. Some patients have difficulty initiating treatment because of anxiety about side effects. In these cases the drug may be increased slowly from a low starting dose, if necessary using the syrup form of fluoxetine or paroxetine, or a benzodiazepine may be used to cover the initiation period.

There is little research evidence to guide a decision on duration of treatment. Studies have shown continued improvement for up to 12 months, and for most disorders there is a significant relapse rate when treatment is stopped [39–41]. Guidelines suggest continuing for 12–24 months if treatment is successful, but a longer duration may be required for some patients (Table 2.5). Treatment disconti-

uation should be carefully planned and it is sensible to slowly taper off SSRIs as a matter of routine.

2.4.1.1.2 SNRIs. Venlafaxine is a serotonin and noradrenaline reuptake inhibitor (SNRI). It shares these properties with the TCAs amitriptyline, clomipramine, and imipramine, but it is the first selective SNRI with low affinity for muscarinic, histaminic, and α -adrenergic receptors. At low doses serotonergic effects predominate, but at higher doses (above 150 mg daily) the reuptake of noradrenaline is also significantly blocked [42]. It is not yet clear whether these noradrenergic effects confer additional benefit in the treatment of anxiety disorders. Venlafaxine is available as immediate- and extended-release (XR) preparations.

There is a large evidence base for the antidepressant efficacy of venlafaxine and increasing evidence for its use in anxiety disorders, including GAD [43], OCD [44], and social anxiety disorder [45], and for anxiety symptoms associated with depression [46]. Side effects on initiation of therapy are similar to those of SSRIs with nausea being the most common, and higher doses can cause elevation of blood pressure. A discontinuation syndrome similar to that seen with SSRIs has been reported. Toxicity causes cardiac conduction problems, seizures, and coma. There is a disputed suggestion that venlafaxine overdose may be associated with a higher mortality than that of the SSRIs [47]. This has led to the U.K. government recommending restriction of its prescription to secondary care [48], which appears a perverse decision when the mortality associated with venlafaxine overdose is substantially less than with other antidepressants, such as the tricyclics, which can be prescribed without restriction [25]. Although metabolized by the hepatic cytochrome CYP2D6, venlafaxine does not inhibit this enzyme and has a low potential for drug interactions.

Other SNRIs have been in development for some time and have recently been marketed on the basis of their antidepressant efficacy. As yet their efficacy in anxiety disorders is unproven, although the SNRI duloxetine was shown to be effective for anxiety symptoms associated with depression [49].

2.4.1.1.3 TCAs. This group includes compounds with actions on a range of neurotransmitter systems. Their antidepressant efficacy is primarily mediated by inhibition of the reuptake of 5-HT and noradrenaline, although side effects such as sedation may also have clinical benefits. Their efficacy in anxiety disorders is supported by a long history of clinical experience and a solid evidence base from controlled trials. Studies support the use of clomipramine (a potent 5-HT reuptake inhibitor) in panic disorder and OCD [50, 51], of imipramine in panic disorder and GAD [52, 53], and of amitriptyline in PTSD [54]. No controlled studies support the use of TCAs in social anxiety disorder.

A meta-analysis of controlled studies suggested superior efficacy of clomipramine over SSRIs in OCD [55], but this has not been demonstrated in direct comparisons, and the use of SSRIs has superseded that of TCAs because of advantages in safety and tolerability [56]. Side effects of TCAs include anticholinergic effects (drowsiness, dry mouth, blurred vision, and constipation), antihistaminergic effects (drowsiness and weight gain), and postural hypotension caused by α_1 -adrenoceptor blockade, as well as the side effects common to SSRIs. Some effects are dose related, and as the usual practice is to titrate the dose slowly upward, this often leads to patients being maintained on subtherapeutic doses. A discontinuation syndrome similar to that with SSRIs is well described, and withdrawal should be tapered. Overdose is associated with a significant

mortality due to hypotension, cardiac arrhythmias, metabolic acidosis, seizures, and coma [25]. Interactions can occur with other drugs with central nervous system (CNS) effects (particularly MAOIs), and with drugs that affect hepatic metabolism.

2.4.1.1.4 Mirtazapine. Mirtazapine has a novel mechanism of action that in theory should promote anxiolytic effects, although solid evidence from studies in anxiety disorders is awaited. It increases synaptic release of 5-HT and noradrenaline via blockade of presynaptic inhibitory α_2 -adrenoceptors as well as blocking postsynaptic 5-HT₂ and 5-HT₃ receptors and H₁ histamine receptors. Mirtazapine has good efficacy for anxiety symptoms associated with depression [57] and in controlled studies was superior to placebo in PTSD [58], equivalent to fluoxetine in panic disorder [59], and reduced social anxiety symptoms in heavy drinkers [60].

The actions of mirtazapine lead to a unique side-effect profile. Important effects are sedation, drowsiness, dry mouth, increased appetite, and weight gain. It does not cause initial worsening of anxiety. Tolerance to the sedative properties occurs after a few weeks, and paradoxically higher doses tend to be less sedating. Overdose does not cause serious toxic effects other than sedation. It has the potential for interaction with drugs that inhibit the cytochrome P450 2D6 and 3A4 isoenzymes, although reports of interactions are rare. Discontinuation symptoms have not yet been reported.

2.4.1.1.5 MAOIs. These drugs increase synaptic availability of 5-HT, noradrenaline, and dopamine by inhibiting their intracellular metabolism. The classical MAOIs phenelzine and tranylcypromine bind irreversibly to monoamine oxidase, while the newer drug moclobemide is a reversible inhibitor of monoamine oxidase A (RIMA). The long history of clinical use of MAOIs in panic disorder, PTSD, and social anxiety disorder is supported by several controlled trials [61–63], whereas the evidence for moclobemide is less conclusive. Both positive and negative studies have been published in panic disorder and social anxiety disorder, and meta-analysis suggests a lower response rate in social anxiety disorder than with SSRIs [64]. Brofaromine, a reversible MAOI, was effective in a controlled trial in social anxiety disorder but is no longer marketed.

The classical MAOIs have a significant side-effect profile, including dizziness, drowsiness, insomnia, headache, postural hypotension, and anticholinergic effects. Asthenia, weight gain, and sexual dysfunction can occur during long-term use. A hypertensive reaction (cheese reaction) may follow the ingestion of foods containing tyramine, which must therefore be removed from the diet. Overdose can be fatal due to seizures, cardiac arrhythmias, and hypotension. Interactions can occur with sympathomimetics, antihypertensives, and most psychoactive drugs, and a washout of two weeks is advised when switching from a MAOI to another antidepressant. Moclobemide is better tolerated, although at high doses (> 900 mg daily) its binding becomes less reversible and dietary restrictions should be observed. The main side effects are dizziness and insomnia. Overdose toxicity is less, although fatalities have been reported.

2.4.1.2 5-HT_{1A} Receptor Agonists. Buspirone is a partial agonist at postsynaptic 5-HT_{1A} receptors in the limbic system but a full agonist at autoreceptors in the raphe [65]. Acute dosage inhibits 5-HT release, but this recovers with continued administration.

It has anxiolytic effects that take several weeks to emerge, although in contrast to antidepressants it does not cause worsening of symptoms at initiation (Fig. 2.4). Buspirone is effective in the treatment of GAD [66] and for anxiety symptoms in depression [67], either as monotherapy or combined with an SSRI. Response is less favorable if the patient has recently taken a benzodiazepine [68]. Evidence is lacking to support the use of buspirone in other anxiety disorders. Other drugs in this class have demonstrated anxiolytic properties in preclinical studies. Gepirone is effective for anxiety symptoms associated with depression [69] and tandospirone is licensed for use as an anxiolytic in Japan.

Buspirone is well tolerated, particularly by the elderly [70]. Common side effects include dizziness, anxiety, nausea, and headache. It does not cause sexual dysfunction and does not appear to be associated with a discontinuation syndrome. Overdose causes drowsiness but not serious toxic effects. A potential for interaction with drugs that inhibit the cytochrome P450 3A4 isoenzyme is not a significant problem in clinical practice. GAD is usually a chronic condition and buspirone is suitable for long-term treatment. Patients should be advised to expect a slow onset of benefits and reviewed regularly in the early stages of treatment.

2.4.1.3 β Blockers. The rationale for using β -adrenoceptor blockers for the treatment of anxiety is twofold: first, for the control of symptoms caused by autonomic arousal (e.g., palpitations, tremor) and, second because of the postulated but poorly understood involvement of central noradrenergic activity in anxiety pathways. There is a history of clinical use of these drugs in each of the five major anxiety disorders, but evidence is lacking from controlled clinical trials, and positive findings have often been superseded by later negative studies. Early trials were carried out with propranolol and the more cardioselective atenolol, which has mainly peripheral effects. The efficacy of atenolol in performance anxiety suggests that not all of the effects are centrally mediated [71]. Recently there has been interest in pindolol, a β Blocker that also blocks 5-HT_{1A} autoreceptors and may promote serotonergic neurotransmission. Studies using pindolol to augment SSRI treatment of anxiety disorders have had mixed results [72–74].

Commonly β blockers cause side effects including bradycardia, hypotension, fatigue, and bronchospasm. Overdose can cause fatal cardiogenic shock. Because of the doubtful evidence for efficacy and poor tolerability and safety, their use in anxiety disorders is limited. They may have a circumscribed role in the prevention of performance anxiety [75].

2.4.1.4 Antipsychotics. This category contains drugs with various mechanisms of action that have clinical antipsychotic effects that are thought to be mediated via antagonism of D₂ dopamine receptors in the limbic system and cortex. They are loosely divided into two groups: older “classical” drugs such as haloperidol and chlorpromazine that are potent D₂ blockers and “atypical” antipsychotics that have a lower affinity for D₂ receptors but also block 5-HT₂ receptors. The history of clinical use of classical antipsychotics as “major tranquilizers” for anxiety disorders has little support from controlled trials [76]. Evidence is greatest in OCD for the augmentation of SSRI treatment with haloperidol [77] and the atypical drugs risperidone [78] and quetiapine [79]. Recent controlled trials have reported benefits for the atypical drug olanzapine in social anxiety disorder [80] and for olanzapine and

risperidone in addition to SSRIs in PTSD [81, 82]. Open studies are reporting efficacy for atypical antipsychotics in other anxiety disorders, and it may be that their clinical use expands in the future. The atypicals have advantages in tolerability and safety over the older drugs, particularly a lower incidence of extrapyramidal movement disorders, although they may cause sedation, weight gain, and metabolic effects. Their metabolism by cytochrome P450 enzymes leads to a potential for interaction with many coprescribed drugs.

2.4.2 Drugs Acting via Amino Acid Neurotransmission

Glutamate is the major excitatory amino acid in the brain and has a key role as a neurotransmitter in memory, learning, and stress responses. Glutamate receptors are present throughout the CNS but differ widely according to their localization and function [83], and as a result have not been easy to identify as targets for pharmacological manipulation (see also Chapters 10 and 11 in Volume I of this handbook). The role of glutamate in facilitating new learning has been established for some time, and it has recently been suggested that augmenting glutamate transmission may enhance recovery from anxiety disorders by accelerating the learning of new, nonanxious responses [84].

GABA is formed by the decarboxylation of glutamate and is the major inhibitory neurotransmitter (see also Chapters 12 and 13 in Volume I of this handbook). Recent research has centered on the role of the GABA_A receptor as the mediator of the anxiolytic and sedative effects of drugs such as alcohol and the benzodiazepines [85]. This complex transmembrane receptor consists of five linked subunits in a ring structure around a central chloride ion channel (Fig. 2.5). Binding of the endogenous neurotransmitter changes the configuration of the receptor, causing an increased permeability to chloride ions and inhibiting neuronal firing. Exogenous drugs bind to different sites on the receptor and affect its function, either in a direct fashion or by modulating the effects of GABA. The structure of the receptor depends on the configuration of its protein subunits, and nearly 20 subtypes have been found in the brain, with differences in topographical distribution and between individuals. Different receptor subtypes have different sensitivity to drugs such as alcohol and

Figure 2.5 The GABA_A receptor.

may explain differences in the sensitivity of individuals to these drugs. Abnormalities of the GABA_A receptor have been identified in humans with anxiety disorders [86].

For most of the second half of the twentieth century the benzodiazepines were the mainstay of the treatment of anxiety. They have now been surpassed by antidepressants in terms of overall efficacy and tolerability, but despite concerns about their long-term safety, they remain an important therapeutic option. The group of anti-convulsants contains a number of drugs that act via GABA or glutamate neurotransmission and have a limited but interesting role in the treatment of particular anxiety disorders.

2.4.2.1 Benzodiazepines. The efficacy of benzodiazepines has been proven in anxiety disorders through extensive clinical experience and controlled trials [87, 88], although it is important to note that they are not effective at treating comorbid depression and there is less evidence to support their use in OCD and PTSD. Their anxiolytic effects have an immediate onset, and in contrast to other groups they do not cause a worsening of anxiety when therapy is initiated (Fig. 2.4). They are generally well tolerated, although side effects such as sedation, loss of balance, and impaired psychomotor performance may be problematic for some patients. There are reported associations with road traffic accidents [89] and with falls and fractures in the elderly [90]. They are relatively safe in overdose [91], although the risk is increased if taken in combination with alcohol or other sedative drugs.

The major controversy surrounding the use of benzodiazepines has concerned the risks of long-term treatment, specifically tolerance, abuse, dependence, and withdrawal effects. From being the most widely prescribed psychotropic drug they suffered a major backlash, although a more balanced view of their place in treatment has subsequently emerged [92] and they continue to be favored by patients and prescribers [93]. After 40 years of clinical experience there is little evidence of tolerance to the anxiolytic effects of benzodiazepines [94]. Abuse (taking in excess of the prescribed dose) is uncommon except in individuals with a history of abuse of other drugs, who may not be suitable for benzodiazepine therapy [95]. There is, however, a consensus that adverse effects on discontinuation are more common than with other anxiolytics [96]. A careful clinical assessment is indicated in this situation, as these effects may be caused by recurrence or rebound (recurrence with increased intensity) of the original anxiety symptoms.

A benzodiazepine withdrawal syndrome has been described in some patients discontinuing therapy (Table 2.6). Although potentially serious, it is generally mild and self-limiting (up to six weeks) but may accompany or provoke a recurrence of anxiety symptoms and cause great concern to the patient. As with any other treatment, the risks and benefits of benzodiazepine therapy should be carefully assessed and discussed with the patient. Monotherapy will not be first-line treatment for the majority of patients, but benzodiazepines offer a valuable option that should not be discounted.

The potential for interactions with other medications comes from two sources: the exacerbation of sedation and impaired psychomotor performance by other drugs also causing these effects and alterations in the hepatic metabolism of benzodiazepines by drugs that are either inducers or inhibitors of cytochrome P450 enzymes. The increased toxicity in combination with alcohol is mostly pharmacodynamic but may partly be due to the inhibition of metabolism of some benzodiazepines by high alcohol concentrations. Other drugs that may have additive effects on sedation include

TABLE 2.6 Benzodiazepine Withdrawal Syndrome

Symptoms	Hyperarousal: anxiety, irritability, insomnia, restlessness Neuropsychological effects: dysphoria, perceptual sensitisation, tinnitus, confusion, psychosis Autonomic lability: sweating, tachycardia, hypertension, tremor, dizziness Seizures
Risk factors	Treatment factors: treatment duration > 6 months/High dose/Short-acting drug/Abrupt cessation Patient factors: severe premorbid anxiety/Alcohol/substance use/disorder/Female/Dysfunctional personality/Panic disorder
Therapeutic strategies	Gradual tapering; switch to long-acting drug, e.g., diazepam; cover with secondary agent (anticonvulsant, antidepressant); cognitive behavioral therapy

TCAAs, antihistamines, opioid analgesics, and the α_2 -adrenoceptor agonists clonidine and lofexidine. Most benzodiazepines undergo oxidative metabolism in the liver that may be enhanced by enzyme inducers (e.g., carbamazepine, phenytoin) or slowed by inhibitors (sodium valproate, fluoxetine, fluvoxamine). Oxazepam, lorazepam, and temazepam are directly conjugated and are not subject to these interactions.

The specific clinical use of the numerous available benzodiazepines depends on their individual pharmacokinetic and pharmacodynamic properties. Drugs with a high affinity for the GABA_A receptor (alprazolam, clonazepam, lorazepam) have high anxiolytic efficacy, and these drugs may have a particular role in panic disorder where subsensitivity of GABA_A receptors has been demonstrated [97, 98]; drugs with a short duration of action (temazepam) are used as hypnotics to minimize daytime sedative effects; diazepam has a long half-life and duration of action and may be favored for long-term use or when there is a past history of withdrawal problems; oxazepam has a slow onset of action and may be less susceptible to abuse.

Guidance on the clinical indications for benzodiazepine therapy is available from various sources [35, 36, 95]. Long-term therapy is most likely to present problems with discontinuation and is usually reserved for cases that have proven resistant to treatment with antidepressants alone. Patients may benefit from a two- to four-week course of a benzodiazepine while antidepressant therapy is initiated, as this counteracts the increased anxiety caused by some drugs [99]. A benzodiazepine may be useful as a hypnotic in some cases of anxiety disorder and can be used by phobic patients on an occasional basis before exposure to a feared situation.

Benzodiazepines are additionally discussed in Chapter 3.

2.4.2.2 Anticonvulsants. There is an overlap between the clinical syndromes of anxiety and epilepsy. Panic disorder and PTSD can present with symptoms similar to temporal lobe seizures, alcohol and drug withdrawal states can cause both anxiety and seizures, and some drugs (e.g., barbiturates and benzodiazepines) act as both anticonvulsants and anxiolytics. Most anticonvulsants act via the neurotransmission of GABA or glutamate and in recent years have offered a promising field for the development of novel anxiolytic therapies [83, 100]. Although preclinical studies have demonstrated their anxiolytic properties, the evidence base in humans is less impressive

and in practice they are reserved for second-line or adjunctive therapy. Drug interactions mediated via hepatic enzymes are a significant feature of this group.

Gabapentin increases GABA activity by a mechanism that is unclear. It causes dose-related sedation and dizziness. It has been shown in controlled trials to be effective in social anxiety disorder [101] and to benefit some patients with panic disorder [102]. Pregabalin is a related compound that has recently demonstrated efficacy in GAD in a phase III study [103].

Lamotrigine blocks voltage-gated sodium channels and inhibits release of glutamate. A controlled study found efficacy in PTSD [104]. Important side effects include fever and skin reactions.

The historical use of sodium valproate for anxiety is poorly supported by clinical trials. A randomized study showed efficacy in panic disorder [105] and benefit has been reported in open studies in OCD and PTSD. The major side effects are tremor, nausea, ataxia, and weight gain and there is the potential for drug interactions via inhibition of hepatic enzymes.

No satisfactory randomized controlled trials have been published demonstrating the efficacy of carbamazepine in anxiety disorders, although it has a history of use as an anxiolytic in panic disorder and PTSD. It has an unfavorable side-effect profile (nausea, dizziness, ataxia) and multiple drug interactions due to induction of liver enzymes. Levetiracetam has anxiolytic activity in preclinical studies and was helpful for patients with social anxiety in an open study [106]. Tiagabine blocks neuronal uptake of GABA and has reported benefits in panic disorder and PTSD [107]. Topiramate has complex actions on GABA and glutamate and was found to be helpful for some symptoms of PTSD [108]. Vigabatrin inhibits GABA metabolism and has been shown to block provoked panic attacks in healthy volunteers [109].

2.4.3 Drugs with Other Mechanisms of Action

2.4.3.1 Antihistamines. The longstanding use in some countries of hydroxyzine, a centrally acting H₁ histamine receptor antagonist, is supported by positive findings in controlled trials in GAD [110–112]. Hydroxyzine promotes sleep and its anxiolytic effects have an early onset. Although it causes sedation, tolerance to this effect often occurs and effects on psychomotor performance are smaller than with benzodiazepines [113]. It is well tolerated and withdrawal effects have not been reported. Although the evidence for its efficacy is not large, hydroxyzine provides an option for some patients with GAD for whom standard treatments are unsuitable.

2.4.3.2 Lithium. Lithium is effective in the treatment of mood disorders. Its mechanism of action is unclear, but is likely to be via modification of intracellular second-messenger systems. There are no controlled trials demonstrating the efficacy of lithium in anxiety disorders, but there have been case reports of its use as an augmenting agent in panic disorder and OCD. Its high toxicity and poor tolerability limit its use in anxiety in the absence of a stronger evidence base.

2.5 PHARMACOTHERAPY FOR ANXIETY DISORDERS

An overview of appropriate drug treatments for each of the major anxiety disorders as well as for depression with prominent anxiety symptoms is shown in Table 2.7.

TABLE 2.7 Pharmacotherapy for Anxiety Disorders

Disorder	First-Line Treatments	Second-Line Treatments	Other Treatments	Augmenting Agents
Generalised anxiety disorder	Venlafaxine 75–150 mg, SSRI (e.g., paroxetine 20 mg, escitalopram, 10 mg)	Imipramine 150 mg, buspirone 15–60 mg	Diazepam 5–30 mg, hydroxyzine 200–400 mg	Benzodiazepines (e.g., diazepam 5–30 mg)
Obsessive-compulsive disorder	SSRI (e.g., fluoxetine 20–60 mg, fluvoxamine 50–300 mg, paroxetine 20–60 mg, sertraline 50–200 mg)	Clomipramine 150–250 mg	—	Haloperidol 5–15 mg, quetiapine 25–600 mg, risperidone 1–3 mg
Panic disorder	SSRI ± benzodiazepine (e.g., citalopram 20–60 mg, escitalopram 5–20 mg, paroxetine 10 mg daily increasing to max 50 mg daily)	Clomipramine 150 mg, imipramine 150 mg, phenelzine 30–60 mg, alprazolam 3–6 mg	Clonazepam 0.5–3 mg, diazepam 5–30 mg, lorazepam 2–6 mg, Gabapentin, 500–1000 mg	Benzodiazepines (e.g., diazepam 5–30 mg), pindolol
Post traumatic stress disorder	SSRI (e.g., paroxetine 20–50 mg, sertraline 50–200 mg)	Amitriptyline 150–200 mg, mirtazapine 30–45 mg, phenelzine 30–60 mg	Carbamazepine 250–500 mg, lamotrigine 100–200 mg, venlafaxine 75–150 mg	Olanzapine 2.5–5 mg
Social anxiety disorder	SSRI (e.g., paroxetine 20–50 mg), venlafaxine 75–150 mg	Phenelzine 30–60 mg	Clonazepam 0.5–3 mg, gabapentin 500–1000 mg, moclobemide 600 mg, olanzapine 2.5–5 mg	Benzodiazepines (e.g., diazepam 5–30 mg), buspirone 20–40 mg
Specific phobia	—	SSRI (e.g., paroxetine 20 mg)	Benzodiazepines (e.g., diazepam 5–10 mg)	—
Depression with concomitant anxiety	SSRI ± benzodiazepine (e.g., paroxetine 20–40 mg), mirtazapine 30–45 mg, venlafaxine 75–150 mg	Amitriptyline 75–150 mg, clomipramine 75–150 mg	—	Benzodiazepines (e.g., diazepam 5–30 mg)

Note: Doses are the suggested total daily dosage.

This overview represents the current view of the authors based on their interpretation of the published evidence and their extensive clinical experience.

2.5.1 Generalized Anxiety Disorder

GAD is a prevalent, chronic, disabling disorder that is comorbid with other anxiety or mood disorders in the majority of cases [114]. While it is a relatively new diagnostic concept, longitudinal studies have reinforced its validity [115]. The core symptoms are chronic worry and tension, and GAD frequently presents with somatic complaints such as headache, myalgia, or insomnia [116]. The diagnosis requires symptoms to be present for at least 6 months, although the duration of illness at presentation is usually much longer than this. The presence of comorbidity leads to a worse prognosis [117]. Cognitive behavioral therapy (CBT) is a structured psychological therapy usually delivered by a trained therapist on an individual basis over 10–15 weekly sessions. It aims to elicit erroneous thinking patterns that lead to anxious thoughts and to train the patient to challenge them and adopt new thinking strategies. CBT has been shown to be effective in GAD and should be considered if available [118].

Recommended drugs for GAD are antidepressants, benzodiazepines, buspirone, and hydroxyzine [114]. The use of antipsychotics is not supported by controlled trials and is discouraged due to their poor long-term tolerability. Pregabalin (related to the anticonvulsant gabapentin) was effective in preliminary trials and may be a future treatment option [103].

Recent evidence has brought about a shift in prescribing in GAD, and now the usual choice for first-line treatment will be an antidepressant. Suitable drugs include venlafaxine [43] and the SSRI paroxetine [119]. A nonsedating TCA such as imipramine could also be used if tolerated and where the risk of suicide is deemed to be low [53]. Little research is available to guide a decision on treatment duration, and a standard recommendation for anxiety disorders would be to continue therapy for at least 12 months following clinical improvement [34]. Buspirone is also appropriate for long-term therapy in the absence of comorbid depression [120].

Benzodiazepines are effective as monotherapy [53] but are rarely used as first-line therapy in this context because of their side-effect profile. They have a useful short-term role for the rapid control of anxiety symptoms or for the control of somatic symptoms such as muscle tension and insomnia, particularly in the early stages of antidepressant therapy. Hydroxyzine has a limited role but can be considered if other treatments are unsuitable [111].

2.5.2 Obsessive-Compulsive Disorder

OCD is a disabling disorder that runs a chronic or recurrent course ([121]; see also Chapter 6). It is diagnosed by the presence of obsessions (recurrent, intrusive thoughts, images, or impulses that are experienced as irrational and unpleasant) or compulsions (repetitive behaviors that are performed to reduce a feeling of unease). The symptoms are present for at least 1 h every day and cause impairment of important functions. Prevalence has been measured in various populations and is around 1–2%. Symptoms start as early as the first decade and have often been present in excess of 10 years at presentation [122]. Depression occurs in more than

50% of cases and there is significant comorbidity with other anxiety disorders, eating disorders, and tic disorders. Although classified with the anxiety disorders, OCD is distinct from the rest of this group in its epidemiological profile and neurobiology. In clinical terms OCD symptoms respond to drugs that enhance serotonergic neurotransmission but not to noradrenergic drugs and poorly to benzodiazepines.

The recommended first-line drugs for OCD are SSRIs and the TCA clomipramine [123]. The required dosage is generally higher than that required for other disorders (e.g., clomipramine 150–250 mg, paroxetine 40–60 mg) and SSRIs have advantages in safety and tolerability. Long-term treatment may be required. There is good evidence for the efficacy of CBT and there may be added benefits from combining psychological and pharmacological therapies [124]. In cases poorly responsive to SSRI treatment augmentation with the antipsychotics haloperidol, risperidone, or quetiapine has support from clinical trials, and addition of buspirone, lithium, and the serotonin precursor L-tryptophan has also been tried. In severe treatment-resistant cases the neurosurgical procedure stereotactic cingulotomy should be considered [125].

2.5.3 Panic Disorder and Agoraphobia

This is also a common, chronic, and disabling disorder with its peak incidence in young adulthood [35]. A panic attack is defined as the sudden onset of anxiety symptoms rising to a peak within 10 min. DSM-IV requires 4 of 13 defined symptoms to be present. The symptoms are physical symptoms corresponding to those caused by autonomic arousal and psychological symptoms (fear of a catastrophic event) and depersonalization/derealization (an altered perception of oneself or the world around). Panic disorder occurs when there are recurrent panic attacks, some of which are uncued or unexpected, and there is fear of having further attacks. Agoraphobia is present in around half of cases [3] and is a poor prognostic indicator. For some patients the anticipatory anxiety or agoraphobia may be considerably more disabling than the original panic attacks. Panic disorder is comorbid with episodes of depression at some stage in the majority of cases [126], with social anxiety disorder and to a lesser extent GAD and PTSD, and with alcohol dependence and personality disorder. Comorbidity results in increased severity and poor response to treatment. Panic disorder is associated with a significantly increased risk of suicide, and this is increased further by the presence of comorbid depression [127].

There is solid evidence for pharmacotherapy for panic disorder with SSRIs [128], the TCAs clomipramine and imipramine [50, 52] and the benzodiazepines alprazolam, clonazepam, lorazepam, and diazepam [129–132]. Therapy is likely to be required for a minimum of 12 months, and the favorable tolerability of SSRIs will usually lead to their choice as first line therapy. Patients with panic disorder are sensitive to drug effects, so a low initial dose may be used and titrated up or a benzodiazepine may be coadministered for the first 2–4 weeks. Stopping treatment is associated with discontinuation effects and an increased risk of relapse and should be approached with caution. CBT is an effective treatment for panic disorder, and additional benefits may be gained from combination therapy [133].

Other drugs effective in controlled studies include the antidepressants phenelzine [61], moclobemide [134], venlafaxine [135], mirtazapine [59] and reboxetine [14] and the anticonvulsants sodium valproate [105] and gabapentin [102].

2.5.4 Post traumatic Stress Disorder

This is another anxiety disorder that is common although underdiagnosed and is usually severely disabling [136]. The diagnosis is given when specific psychological and physical symptoms follow exposure to a traumatizing event that invokes fear, horror, and helplessness. Symptoms fall into three categories: reexperiencing phenomena (flashbacks, nightmares, distress when memories of trauma are triggered), persistent avoidance of triggers to memory of the trauma and general numbing, and hyperarousal (insomnia, irritability, poor concentration, hypervigilance, increased startle response). Symptoms must persist for more than one month after the trauma. PTSD is highly comorbid with depression [137] and substance use disorders and is associated with previous exposures to trauma and a previous history of anxiety disorders. PTSD carries the highest risk of suicide among the anxiety disorders [138]. Without effective treatment it generally runs a chronic, unremitting course.

The evidence base for pharmacotherapy is shallow although improving. Efficacy is established for the SSRIs paroxetine [139], fluoxetine [140], and sertraline [141] and the TCA amitriptyline [54]. Treatment is started at standard dose but may be titrated upward (e.g., paroxetine 20–50 mg). Results from long-term studies are awaited, but treatment should be continued for a minimum of 12 months. Medication is given alongside psychotherapy, usually cognitive and exposure therapies [142]. Other treatments include the antidepressants phenelzine and mirtazapine, the anticonvulsants lamotrigine, sodium valproate, carbamazepine, and tiagabine, and augmentation with the atypical antipsychotic olanzapine. The use of benzodiazepines is not advised as their efficacy is not established and withdrawal symptoms may be particularly distressing. If insomnia is problematic, then a nonbenzodiazepine hypnotic may be prescribed.

2.5.5 Social Anxiety Disorder (Social Phobia)

This disorder is characterized by anxiety symptoms in social or performance situations accompanied by a fear of embarrassment or humiliation. Situations are avoided or endured with distress. There may be a specific fear of one or two situations (most commonly public speaking) or of three or more situations in the generalized subtype. Epidemiological studies find this to be the most prevalent anxiety disorder among the general population [143]. Peak onset is around the time of adolescence and the resulting impairments can have a profound effect on social and occupational development. If untreated it tends to follow a chronic, unremitting course. Social anxiety disorder is frequently comorbid with depression, other anxiety disorders, alcohol problems, and eating disorders. It is associated with an increased rate of suicide that is significantly higher in the presence of comorbidity [144].

Drug treatment studies have focused on the generalized subtype [145]. The largest evidence base is for the SSRIs, which are accepted to be the drug treatment of choice. Treatment is started at standard dose and increased as necessary (e.g., paroxetine 20–50 mg). Duration of treatment is usually for at least 12 months, and there is benefit from combination with CBT [146]. The other class of antidepressant to be considered is the MAOIs, as phenelzine and moclobemide have controlled trial data to support their use [63]. TCAs have no proven efficacy and evidence for venlafaxine and mirtazapine is awaited. Among the benzodiazepines only clonazepam has been

shown to be effective as monotherapy, possibly due to its effects on 5-HT_{1A} receptors [147]. Benzodiazepines may also be used to augment SSRI treatment. Other drugs to consider are the anticonvulsant gabapentin and the antipsychotic olanzapine. The β blockers are not effective in generalized social anxiety disorder but have a role in symptomatic control in specific performance anxiety.

2.5.6 Specific Phobia

In this disorder the patient has an inappropriate or excessive fear of a particular stimulus or situation, such as animals, heights, or thunder. An anxiety reaction is consistently and rapidly evoked on exposure to the stimulus, and there is anticipatory anxiety. Population studies have found a surprisingly high prevalence and associated disability, for example a lifetime prevalence of 12% in the National Comorbidity Survey [143]. The standard treatment for specific phobia is behavioral therapy, and patients rarely require pharmacological treatment. Nevertheless there are clinical and pharmacological similarities between patients with specific phobias and those with other anxiety disorders, particularly panic disorder [148], and it might be predicted that anxiolytic medications would have beneficial effects. A small controlled study found an improvement in measures of fear and avoidance after a four-week trial of the SSRI paroxetine [149], and there is also a role for the use of a short-acting benzodiazepine to control anxiety prior to exposure to the feared stimulus. A further interesting finding with potentially wider application is that the benefits of psychological therapy for height phobia were increased by the use of D-serine, a drug that enhances *N*-methyl-D-aspartate (NMDA) glutamate receptor functioning [150]. This may have been due to the effects of this drug in promoting learning and “over-writing” of conditioned phobic responses.

2.5.7 Anxiety Symptoms in Depressive Disorders

The prevalence of depression in patients with anxiety disorders is high, as is the prevalence of anxiety in patients with depression [151, 152]. Among patients presenting for treatment of anxiety symptoms, a large proportion will have a primary diagnosis of depression. In these situations it is critical to offer a treatment plan that will prove effective against both anxiety and depression [153]. The presence of both disorders together causes an increase in disability, increased severity of symptoms, a higher likelihood of suicidal thoughts, and a poor response to treatment [154].

Antidepressants would be the obvious drug class to select in this patient group, and a number of controlled studies have demonstrated their efficacy. Both SSRIs and TCAs are effective, with the most evidence being for the SSRI paroxetine and the TCAs clomipramine and amitriptyline [155–157]. Comparative studies favor the SSRIs because of their better tolerability, and safety is also a factor in a group at high risk of suicide. Recent studies have demonstrated the efficacy of the new antidepressants venlafaxine [46] and mirtazapine [57] in this group, and as their tolerability matches that of the SSRIs, they should also be considered as first-line treatment. Benzodiazepines produce a rapid improvement in anxiety but are ineffective at treating depression [158] and are not suitable for long-term treatment in this context. They have a short-term role on initiation of antidepressant therapy in selected patients.

2.6 CONCLUSIONS AND FUTURE DIRECTIONS

We have demonstrated that the recent shift in clinical practice toward the use of antidepressants, particularly SSRIs, for the first-line treatment of anxiety disorders is supported by research evidence from randomized controlled trials. Although there has been some negative reporting of the use of SSRIs, the overall situation with regard to anxiety disorders remains one of underdiagnosis and undertreatment, so it should be expected that SSRI use will continue to increase. Clinical practice may be refined in future years as important gaps in the current knowledge base are filled, including the optimal duration of treatment, the identification of patients at particular risk of relapse, the benefits of combining drugs with psychotherapy, and suitable options for patients resistant to first-line treatments. Health policy in the United Kingdom appears to be shifting toward the management of anxiety disorders in primary care [37], and this may potentially lead to an increase in provision of psychological therapies and further raise the profile of anxiety disorders.

New drugs available for the treatment of depression may also prove to be effective for anxiety disorders. In the immediate future these will be drugs acting on the monoamine system. While the prime position of the SSRIs has been reinforced by evidence for the role of 5-HT in anxiety, newer antidepressants such as the SNRIs and mirtazapine have a dual action on serotonergic and noradrenergic neurotransmission. This dual action appears to confer additional benefits in the treatment of depression, but it is not yet clear whether the same is true in anxiety disorders. Further clinical studies are required to fully define the role of venlafaxine and mirtazapine, and clarification of the role of noradrenaline in anxiety is likely to occur.

Many other drug groups with actions on monoaminergic neurons have demonstrated anxiolytic properties in preclinical studies and may in the future prove to be effective treatments. The most likely candidates at present are the azapirones, which are partial agonists at 5-HT_{1A} receptors and have already demonstrated antidepressant and anxiolytic activity in humans [65]. Other potential candidates include the 5-HT_{2C} receptor antagonist and melatonin receptor agonist agomelatine [159], other 5-HT_{2C} antagonists [160], 5-HT_{1B} receptor agonists and antagonists [161] and 5-HT₄ antagonists [162].

It is only in recent years that drugs acting via GABA neurotransmission have been supplanted as first-line treatments, and new drugs in this class with improved tolerability compared to the benzodiazepines are likely to be marketed in the near future [163]. Other GABAergic drugs already marketed for their anticonvulsant properties, such as the selective GABA reuptake inhibitor (SGRI) tiagabine, may prove to have useful efficacy in anxiety disorders [164]. Further down the line agonists that are selective for specific subunits of the GABA_A receptor offer the prospect of drugs that are anxiolytic but with fewer sedative properties [165].

Overall it is remarkable that current pharmacological strategies are centered around such a small number of brain mechanisms. Future strategies may involve glutamate neurotransmission, particularly inhibition of mGlu5 receptors [166], and neuropeptides such as corticotropin-releasing factor antagonists ([167]; see also Chapter 5) and substance P antagonists [168, 169]. A continued expansion in the range of anxiolytic therapies should be anticipated.

3.1 INTRODUCTION

The widespread use of benzodiazepines (BZs) is largely due to their powerful anxiolytic and hypnotic properties in combination with safety even at high dosages when used alone without other central nervous system (CNS) depressant drugs or alcohol. Strictly speaking, only the 1,4- and 1,5-benzodiazepines (Figs. 3.1–3.3) belong to this class of compounds. But since the development of chlordiazepoxide (see below), a large number of chemically unrelated groups of tranquilizers have been

Figure 3.1 Structure of 1,4-benzodiazepines. Shown are several subtype non-selective 1,4-benzodiazepines as well as two ligands with some preference for α_1 -containing GABA_A/BZ receptors (quazepam and 2-oxoquazepam).

Figure 3.2 Structure of two triazolo-1,4-benzodiazepines and midazolam. All compounds shown are non-selective to various GABA_A/BZ-receptor subtypes.

synthesized which act with high affinity and specificity via the BZ receptor sites. Among the most important classes are the triazolopyridazines (e.g., CI 218,872; Fig. 3.4), imidazopyridines (e.g., zolpidem; Fig. 3.4), and β -carbolines (e.g., β -carboline-3-methylester; Fig. 3.4).

The first known and intensively studied synthetic tranquilizers were the barbiturates meprobamate, reserpine, and chlorpromazine. In an attempt to circumvent the molecular manipulation approach and to obtain a novel chemical type of tranquilizer, Leo H. Sternbach and colleagues, who developed the first BZ compounds, did not start from a biochemical or pharmacological point but from the viewpoint of a chemist in that

Zaleplon

β -Carboline-3-methylester

Figure 3.4 Structure of some non-BZ ligands of GABA_A/BZ receptor. CL 218,872 is the prototypical α_1 -preferring ligand. As well, β -carboline-3-methylester is a long-known α_1 -preferring ligand, but in contrast to CL 218,872, it is a full negative modulator. Zolpidem is the most selective GABA_A/BZ receptor ligand known binding with high affinity only to α_1 -containing receptors and with moderate affinity to α_2 - and α_3 -containing receptors. Zaleplon and zopiclone are less selective than the former two but still do not display the full functionality of the classical 1,4-BZs.

he postulated that the structures should be more or less unexplored, be easily obtainable, and be demanding for a synthetic chemist [1]. Even more so, their discovery was not the planned synthesis of a given structure but the result of an unexpected chemical reaction. Thus, the structure of the first in this series of tranquilizers, generically named chlórdiazepoxide and marketed as Librium, was only established some time after its synthesis and after it had been shown to be an efficient minor tranquilizer.

Twenty years after the first human in vivo pharmacological testing the molecular targets of BZ ligands were simultaneously described by three groups using [^3H]diazepam as a tool [2–4]. Since then, research into the action and function of BZ has taken advantage of the ease with which the ligands can be measured in vivo and in vitro using their tritiated forms. The novel selective labeled ligands, in conjunction with the development of molecular biology techniques, paved the ground to study the biochemical and neurobiological functions of the BZ in such detail that they are now among the best understood neuropharmacological agents.

Even before the BZ binding sites were described on a molecular level, it was speculated that γ -aminobutyric acid (GABA) plays a crucial role in the central action of BZ [5, 6]. Gradually, a picture evolved in which neuronal BZ binding sites were physically coupled to GABA type A (GABA_A) receptors to form the GABA_A /BZ receptor complex [7–9]. This model was further proven by demonstrating that affinity-purified BZ receptors contain sites for the specific GABA_A agonist [^3H]muscimol [10]. On sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) the purified protein separated into two major bands, labeled α (50 kDa) and β (57 kDa). By irreversibly photolabeling BZ receptors with [^3H]flunitrazepam the 50-kDa band is strongly labeled, but tissue-specific heterogeneity of the central BZ receptor was demonstrated by showing that other than the α and the β bands specifically incorporated [^3H]flunitrazepam [11]. Only the introduction of the molecular binding techniques finally settled the issue and started a new area in BZ ligand development and GABA_A /BZ receptor research.

Shortly after the discovery of BZ binding sites in the CNS, specific high-affinity [^3H]diazepam binding was described in various peripheral tissues and in transformed cells of neuronal origin [4, 12]. These sites are physically and pharmacologically distinct from sites present in tissues derived from the neuronal crest during ontogeny [13–15]. Though diazepam (Fig. 3.1) and most other clinically important BZs [16] bind with high affinity to both sites, other BZ ligands preferentially recognize one or the other: The 4'-chloro-substituted diazepam (RO 5-4864) and the isoquinoline Pk 11195 recognize only the “peripheral-type” site, while flumazenil (RO 15-1788, Fig. 3.3) and clonazepam (Fig. 3.1) are specific ligands for the “central-type” BZ site. The distribution of the “central-type” receptors made them likely candidates for the therapeutic action of the BZs; the peripheral sites were originally termed “acceptors” to denote a lack of physiological or pharmacological function [17]. Since then, the peripheral-type BZ receptor protein was shown to be located in the outer mitochondrial membrane [18] and to be most likely involved in cholesterol uptake and steroid exchange across that membrane [19, 20]. It is an 18-kDa protein with five transmembrane α -helical domains [see 21], clearly different from subunits of the GABA_A receptor. This BZ recognition site is unlikely to be involved in the central action generally associated with BZ. Therefore, the remainder of the text will concentrate on the GABA_A /BZ receptors. For a more detailed discussion on the structure of GABA receptors, see Chapter 12 in volume I of this handbook.

3.2 PHARMACOLOGY OF BENZODIAZEPINE RECEPTOR LIGANDS

3.2.1 Therapeutic Action of BZ Receptor Ligands

The 1,4-BZs exhibit remarkably similar clinical profiles, demonstrating anxiolytic, sedative, myorelaxant, anticonvulsant, amnestic, and respiratory depressant properties. However, there is a separation in the doses needed to achieve these effects, though the size of the therapeutic window differs slightly between different BZs. Only when it comes to receptor subtype selective compounds can sedation be more prevalent than any of the other effects (see Fig. 3.5).

A large number of new BZ receptor ligands have been evaluated preclinically and clinically in recent years, all of them structurally different from the classical 1,4- and 1,5-BZs. These compounds include the hypnotic agents zolpidem, zaleplon, and zopiclone (Fig. 3.4). The imidazopyridine zolpidem is a highly potent sedative and hypnotic [22]. In contrast to the classical BZ it does not seem to alter sleep architecture or induce rebound insomnia after discontinuation [23, 24]. Zolpidem decreases sleep latency and increases sleep duration and reduces the number of awakenings [25]. Zolpidem has rapid metabolism with metabolic elimination $T_{1/2\beta}$ values of 1.5–3 h, and when used at normal evening doses to treat insomnia, the residual cognitive impairment effects the next morning are negligible. While zaleplon may be best indicated for the delayed onset of sleep, zolpidem and zopiclone may be better indicated for maintaining a complete night's sleep [26]. For a detailed discussion on the hypnotic properties of benzodiazepines, see Chapter 6 in volume III of this handbook.

BZs are relatively safe, even in large doses. However, especially when administered together with other sedative substances, that is, ethanol, barbiturates, or opiates, toxic effects may result. These include general apathy, muscular atonia, ataxia, and inhibition of the respiratory system. Under severe intoxication flumazenil can be given as an antidote, though care must be taken as this compound has a much shorter

Figure 3.5 Correlation of activity at GABA_A receptors with clinical effects. The intrinsic activity of BZ receptor ligands ranges on a continuum from full positive (top) to full negative modulators (bottom). Receptor-subtype-specific compounds with the less than full efficacy may avoid unwanted GABA-mediated effects.

half-life than many other BZ ligands in clinical use, which might make the repeated administration necessary.

3.2.2 Endogenous Benzodiazepine Site Ligands

Ever since the discovery of the BZ receptors, scientists have been interested in finding endogenously produced substances that would act naturally via these binding sites and would be called endozepines. Many substances have been described that interfere with BZ binding [27–29], but a definitive proof of physiological significance of any of these compounds is still missing. Without going into details of each putative compound, a few of them are still being investigated and may finally prove to be active endogenous BZ ligands, at least in certain pathophysiological conditions.

It has been clearly demonstrated that 1,4-BZs are present in the body and brain, even in postmortem brains from patients deceased 20 years before the first BZs have been synthesized [30, 31], suggesting that, for example, *N*-desmethyldiazepam could be formed by endogenous enzymes. These pathways have been poorly characterized in humans, and, therefore, the compounds might originate from plants or bacteria known to be able to synthesize BZs. As well, BZ ligands with negatively modulating properties may be endogenously formed from the β -carboline series of compounds [32], although some of the early compounds isolated from urine may not be present in brain or be artifacts of the isolation procedure [33, 34].

One of the most interesting cases has been the discovery of a peptide of about 100 amino acids called diazepam binding inhibitor (DBI). DBI was suggested to act as an endogenous inverse agonist at GABA_A/BZ receptors [35, 36]. It is a competitive inhibitor of [³H]flumazenil binding to central GABA_A receptors and to [³H]RO 5-4864 binding to peripheral-type mitochondrial BZ receptors [37]. It is present in several different forms and mostly in brain glial cells and tumors and in peripheral tissues [38, 39]. Interestingly, DBI was found to be a member of the acyl-coenzyme A (CoA) binding protein family (ACBP [40, 41]), which have been implicated in many cellular functions including the modulation of acyl-CoA concentrations within cells and are considered products of widely conserved housekeeping genes. The gene also contains a sterol regulatory element [42], which allows DBI/ACBP to be regulated with other genes affecting lipid metabolism. DBI/ACBP has also been shown to activate steroidogenesis by facilitating cholesterol transport to the inner mitochondrial membrane, a process mediated by the peripheral-type BZ receptor [43, 44]. Thus, DBI is a ligand for the mitochondrial BZ receptor but might not be so relevant as an endogenous BZ acting on the central GABA_A receptors. Since various BZ molecules have very variable affinities to the peripheral sites (see above), the behavioral and physiological actions of all these drugs cannot be mediated by these sites.

Stupor associated with hepatic encephalopathy has been treated with flumazenil [45–47], and while amelioration of the symptoms has been observed, it is apparently not so effective to become the only routine therapy [48]. Its efficacy indicates increased amounts of endogenous BZs in these patients, which has been confirmed both in patient samples and from tissues of animals with hepatic failure. The identities of the increased endogenous ligands are not yet settled, but they include BZ like structures and DBI-like peptides [49–52]. Furthermore, in acute intermittent porphyria there are increased concentrations of hemoglobin metabolites, of which hemin and protoporphyrin IX have been shown to potentiate at micromolar

sensitivity the GABA responses of the $\alpha_1\beta_2\gamma_2$ GABA_A receptors via flumazenil-sensitive BZ sites [53]. Interestingly, the latter compounds are also known to have even higher affinities toward the guinea pig brain peripheral-type BZ receptors [54].

The physiological relevance of the naturally produced BZs or other endogenous ligands still remains unclear, but from the experimental point of view it should be kept in mind that the recent BZ site point-mutated mouse models (see below) have not revealed clear behavioral or physiological alterations without drug challenges. This fact does not support any major role for the endogenous BZ site ligands in normal brain function, although they might be involved in pathological conditions, such as hepatic encephalopathy.

3.2.3 Modulation of Single-Cell GABA Response by Benzodiazepines

Detailed analysis of single-channel kinetics confirmed early reports [55] that BZs do not affect GABA-induced single-channel conductance or the average channel open duration [56–58] but increase channel-opening frequency by elevating the number of bursts [56, 57]. Zolpidem has little or no effect on mIPSC frequency, rise time, or amplitude but causes a significant prolongation of the miniature inhibitory postsynaptic current (mIPSC) decay [59]. The negative modulatory β -carboline DMCM (compare β -CCM in Fig. 3.4) reduces the channel-opening frequency without altering open duration or channel conductance; that is, it behaves inversely to positive modulating BZ [58]. BZ potentiation of the GABA response is discussed as originating from an increased affinity for GABA (Fig. 3.6). In this case, BZ should increase the average channel open duration as is observed with increased GABA

Figure 3.6 Effect of positive and negative modulators at BZ recognition site. Positive modulators shift the dose–response curve of GABA at a given GABA_A receptor subtype to the left, whereas negative modulators right shift the curve. At the level of spontaneous inhibitory postsynaptic currents, the modulators mainly affect the current decay. Neither class has any effect on the maximal response of GABA or any effect in the absence of GABA, that is, the endogenous neurotransmitter controls the postsynaptic effect, unless the synaptic GABA release fails to saturate the postsynaptic receptors.

concentrations [56], but kinetic analysis [57] does not support such a mechanism [58]. The increased channel-opening frequency might be explained by an increased affinity at only one of multiple binding sites, different transitions into desensitized states, or altered coupling between binding site and channel [56].

In view of the close to saturating concentrations of GABA in the synaptic clefts of most neurons, BZ receptor ligands might exert their effects mainly by an increase in the decay time constants, thus prolonging the action of GABA [60]. In some neurons, the number of GABA_A receptors in their synapses differ and BZ can increase the mIPSC amplitudes in those synapses with a high number of receptors apparently not saturated by released GABA, while no amplitude potentiation takes place in the synapses with low GABA_A receptor number [61]. BZs can also act on extrasynaptic receptors (e.g., [62]), where the surrounding GABA concentrations are insufficient to cause the maximal effect, although quite a number of extrasynaptic receptors are BZ nonsensitive as they lack the γ_2 subunits [63].

The actions of BZ on GABA_A receptors at single receptor and synapse levels must finally be converted to effects on activities of neuronal pathways and circuitries, which then affect widespread physiological and mental processes.

3.2.4 Tolerance and Dependence to BZ

The GABAergic system has been implicated in the mechanisms of drug abuse, in the abuse not only of BZ-positive modulators but also of other drugs of abuse, such as ethanol, opioids, cannabinoids, nicotine, and stimulants [64]. This is of no surprise, since the GABAergic system is so widespread and regulates most brain systems. Furthermore, novel mechanisms via GABAergic pathways have been proposed to be responsible for the rewarding actions of GABA_A receptor-positive modulators and antagonists after intracerebral injections into different regions of ventral tegmental and caudal hypothalamic regions [65–67]. Effects of chronic use leading to tolerance and abuse to BZ compounds can be examined at the levels of GABA_A receptor sensitivity, receptor subunit alterations, and counteracting adaptations in other neuronal systems.

Chronic treatment of experimental animals or neuronal cell cultures with BZ agonists have shown that the receptor binding determined by various ligands does not alter much [68, 69], suggesting that GABA_A receptor subunit levels are rather stable even during continued receptor stimulation. Similar disappointing results have been obtained when receptor subunit gene transcription has been evaluated by subunit-specific oligonucleotide probes for messenger RNA (mRNA) [70], indicating that the receptor subunit synthesis remains mostly stable. In addition, subunit switches, such as a general change in dominance from γ_2 to δ subunit-containing receptors, have been excluded [70]. Still, there has been a more consistent finding of reduced GABA sensitivity after BZ treatment, especially a reduced or even abolished GABA stimulation of [³H]BZ binding [68, 71], indicating that, while the binding sites are intact, they are in a state where allosteric interactions can no longer facilitate receptor function. Along this line, a similar loss of potentiation after chronic BZ treatment has been observed in the GABA actions stimulated by BZ [68]. It is possible that the reduced coupling between GABA_A receptor binding site domains by chronic treatments is due to altered posttranslational processing of receptor subunits/subtypes and/or by receptor endocytosis, as it can take place rapidly within a few hours [72].

On the other hand, some research groups have been able to find defined alterations in brain regional GABA_A receptor subunit expression, which might correlate with the emergence of tolerance to various BZ agonists. In frontoparietal motor and somatosensory cortex of rats, at least α_1 -subunit expression decreased and that of α_3 , α_5 , $\beta_{2/3}$, and γ_2 subunits increased in a region-selective manner during a 14-day diazepam treatment that resulted in tolerance [73]. The suggested antipanic compound alprazolam alters the expression of brain stem α_3 -, β_1 -, and γ_2 -subunit expression in rats [74]. A defined reduction in the hippocampal α_5 -subunit expression in mice has been suggested to be mainly responsible for the tolerance development to low doses of diazepam [75], in keeping with earlier experiments showing reduced binding of the α_5 -subunit-selective ligand [³H]RY-80 in the hippocampal CA1 region in rats after flurazepam treatment [76]. Thus, it seems that there are several receptor-subtype-dependent mechanisms for tolerance development, partly depending on the animal species and behavioral assays used for tolerance assessment, and conditioning mechanisms, as hinted by the involvement of the hippocampal receptor subtypes. These mechanisms might thus be brain region specific. However, we also need more receptor-subtype-selective functional studies to understand the brain pathways involved in the BZ tolerance mechanisms.

The apparent diversity of the mechanisms accounting for BZ tolerance is further complicated by adaptations in other mechanisms than the GABA_A receptor. Acute diazepam administration at low sedative doses induces the expression of several genes in the cerebral cortex of mice, including growth factors, such as brain-derived neurotrophic factor, and transcription factors and kinases [77]. Interestingly, calcium/calmodulin-dependent protein kinase II remained upregulated at least 40 h after a single diazepam dose. All these changes were dependent on the α_1 -subunit-containing receptors as they were absent in α_1 (H101R) knockin mice. One of the most interesting findings has been the increased function and protein levels of α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)-type glutamate receptors in the hippocampus during chronic treatment with flurazepam or diazepam [78–80]. Especially the GluR-A (GluR-1) subunit of AMPA-type glutamate receptors has been upregulated in certain brain regions by many other drugs of abuse, such as morphine, cocaine, and amphetamine [81–84]. This indicates that the AMPA receptor facilitation, upregulation, and/or increased cell surface targeting are not specific for BZ tolerance or withdrawal. These non-GABA_A receptor adaptations might become important targets for reducing tolerance, dependence, and withdrawal phenomena to BZs and other drugs of abuse.

Most of the dependence experiments have been carried out with long-acting BZ ligands, such as diazepam and flurazepam. However, all full agonists, independent of the duration of action, possess the property of inducing tolerance and dependence. Importantly, the partial agonists so far studied usually do not induce strong tolerance or withdrawal symptoms at experimentally relevant doses [85–88]. However, as none of these has passed into clinical use, we can only refer to these reviews on these compounds.

3.2.5 Metabolism of BZ Receptor Ligands

As detailed before, the pharmacological action of all chemically related BZs in clinical use is similar with the exception of the antagonist flumazenil, though minor variations in the affinity and efficacy between the various subtypes have been

reported. As these minor differences in the receptor actions between the ligands are unlikely to explain all observed clinical variances, they may be mainly or even exclusively due to differences in the absorption and metabolism of the drugs. As even the absorption is close to complete for most of the BZ receptor ligands of this chemical class, most differences can be traced back to the respective metabolic paths. After oral administration the time to peak levels detected in the plasma ranges from 30 min (~ 1 h for diazepam) up to 8 h. As well, the biological half-life of BZ varies greatly between a few hours (e.g., alprazolam, brotizolam) and more than 20 h (e.g., diazepam). As many BZs are extensively metabolized by the cytochrome P450 system in the gastrointestinal tract and liver and, furthermore, many of the metabolites are pharmacologically active, the duration of action of a BZ administration is often unrelated to the biotransformation of the parental compound. Two extreme examples are diazepam and flurazepam with their main and bioactive metabolites *N*-desmethyl-diazepam (nordiazepam) and *N*-desalkyl-flurazepam, respectively, which are eliminated from plasma with half-lives of 80–100 and 50 h, respectively. These differences readily explain that ultra-short-acting ligands are more suitable for the induction of sleep, longer acting ones suited for sleep maintenance and sedation, and very long acting BZ ligands for long-term treatment of anxiety, respectively.

All BZ compounds with nonfused substitutions at position 1 or 2 of the seven-membered ring, like diazepam and flurazepam, undergo a rapid modification of this substituent, resulting in the active NOR metabolites (NOR = *nitrogen ohne radikal*, German, meaning a nitrogen without any substituent). Thus, given the structural similarity of the BZ it is not surprising that quite a number of metabolic pathways converge on nordiazepam (Fig. 3.1). This compound can be metabolized to the active oxazepam by hydroxylation at position 3 of the diazepine ring before it is finally inactivated through glucuronidization at this hydroxyl position and excreted. As for compounds with a fused ring between positions 1 and 2 (midazolam, triazolam, and alprazolam; Fig. 3.2), the first step in inactivation cannot be performed and they are directly hydroxylated, glucuronidized, and excreted.

Non-BZ compounds such as the hypnotics zaleplon, zopiclone, and zolpidem (Fig. 3.4) are generally rapidly absorbed and reach their maximal concentrations within 1–2 h. Zopiclone is extensively metabolized by N demethylation, N oxidation, and decarboxylation. Its chiral center leads to stereoselective pharmacokinetics. Zolpidem is oxidized in the methyl groups and hydroxylated in the imidazolepyridine ring system [89].

Cytochrome P450 (CYP) 3A4 oxidase, located in the enterocytes of the small bowel and liver hepatocytes, is involved in the metabolism of a number of BZ receptor ligands, especially midazolam, triazolam, alprazolam, diazepam, flunitrazepam, and zopiclone [90–92]. The enzyme is inhibited by a number of other drugs, including the antidepressants fluoxetine and nefazodone, the macrolide antibiotic erythromycin, antifungal azoles, and the human immunodeficiency virus (HIV) protease inhibitor ritonavir as well as grapefruit juice. In the context of the mentioned BZ receptor ligands inhibition of CYP3A4 may lead to prolonged sedation, especially when patients are under stable drug treatment and one of the inhibitors is added. For example, midazolam plasma levels (i.e., areas under the curve) at the same dose can vary 400-fold depending on whether CYP 3A4 inhibitor (e.g., itraconazole) or inducer (e.g., rifampicin) is being coadministered [93], which produces clear effects on its clinically wanted sedative and unwanted motor-impairing actions.

3.3 GABA_A/BENZODIAZEPINE RECEPTORS

3.3.1 Subunit and Subtype Structural Diversity

GABA_A receptors are members of the superfamily of ligand-gated ion channels which should be termed Cys loop receptors in order to exclude the structurally unrelated ionotropic glutamate receptors. They are heteropentameric ion channels, although the initial purification of bovine GABA_A receptors suggested that only two proteins are involved in the formation of these Cys loop receptors [10]. Now it is common knowledge that GABA_A receptors are composed of an array of polysubunits (α_{1-6} , β_{1-3} , γ_{1-3} , ϵ , δ , π , and θ), all of which are products of separate genes [94–96]. Their variety is even intensified by several splice forms, for example, α_6 , β_2 , and γ_2 subunits.

The ρ_{1-3} subunits mainly or exclusively present in the retina show similar structural characteristics and exhibit a high sequence identity to the above-mentioned subunits. They are picrotoxin sensitive but insensitive to bicuculline, the prototypic competitive GABA_A antagonist, and to baclofen, the prototypic GABA_B receptor agonist, and have thus been classified as GABA_C receptor subunits [97, 98]. The classification of GABA_A and GABA_C receptors basing on a single pharmacological characteristic is controversial as only few features are common to all GABA_A receptors. Thus, Kai Kaila proposed the terms GABA_i and GABA_m for GABA_A + GABA_C and GABA_B receptors, respectively, with *i* standing for ionotropic and *m* for metabotropic (personal communication to HL).

Common features of all these subunits as well as for the glycine and nicotinic acetylcholine receptor subunits include four putative transmembrane regions and the so-called cysteine loop, located in the N-terminal extracellular domain and characterized by two cysteine residues spaced by 13 otherwise largely divergent amino acids which gave the group its name. Another hallmark of GABA_A receptors is a conserved sequence in the second transmembrane region encompassing the amino acids TTVLTMTT. Though this sequence has been used to retrieve 13 of the known GABA_A receptors [99], it is only partially conserved in the more recently identified subunits ϵ , π , and ρ_{1-3} and hardly recognizable in θ . In view of the fact that five of the eight amino acids are possibly lining the ion channel proper [100], the divergence of the ϵ and θ subunits warrants further investigation into the channel properties of receptors containing these subunits. However, with respect to BZ neither the ϵ nor the θ or δ subunits confer sensitivity to these ligands and the resulting receptors have not been shown to respond to these ligands. All subunits contain recognition sites for N glycosylation in the so-called large intracellular loop between transmembrane regions 3 and 4. The glycosylation adds to the theoretical molecular weight of the subunits, which ranges from 52 kDa for the unprocessed α_1 subunit, that is, still containing the 20- to 30-amino-acid-long leader sequence necessary for plasma membrane targeting, and 62 kDa for the α_4 subunit. This varies only marginally between mammalian species (e.g., between man, mouse, or rat), as the sequence identity between these species is mostly higher than 98%. Furthermore, no substantial pharmacological differences have been observed between the mentioned species. Exceptions to the rule are the non-BZ-relevant ϵ and θ subunits, which display only about 70% sequence identity between human, mouse, and rat [96].

BZ receptor-positive modulator ligands, such as diazepam, CL 218,872, and zolpidem, distinguish two GABA_A receptor subtypes differing mainly in their α - and

γ -subunit variants [101]. They characteristically display a high affinity to the α_1 -subunit-containing receptors, but CL 218,872 and zolpidem differ from diazepam in having reduced affinity to α_2 -, α_3 -, and α_5 -containing receptors [102, 103]. All these ligands are inactive at α_4 - and α_6 -subunit-containing receptors. This classification can be extended further, since some $\alpha\beta\gamma$ combinations differentiate between these ligands: zolpidem binds with poor affinity to α_5 - and/or γ_3 -subunit-containing receptors [104], while CL 218,872 has 10-fold higher affinity (low nanomolar) toward $\alpha_1\beta_3\gamma_3$ receptors than to any other α_1 - or $\gamma_{2/3}$ -subunit-containing receptors. The functional significance of this interaction has not been studied, but if existing at all in native brain, it represents only a minor pool of receptors as CL 218,872 fails to distinguish any high-affinity components in displacement analysis with rat hippocampal and cerebrocortical receptors [105]. This is but one example of the special properties that can be observed in recombinant receptors but does not seem to exist in appreciable amounts in native brain. It is important to note that the behavioral profiles of diazepam, CL 218,872, and zolpidem are quite different and their behavioral efficacy cannot be deduced from competitive ligand binding assays. Thus, CL 218,872 is a low-efficacy anxiolytic, diazepam a potent anxiolytic, and zolpidem a very potent hypnotic with little anxiolytic efficacy. These differences may be explained by their efficacies: CL 218,872 is a partial positive modulator, diazepam a wide-range full-partial positive modulator, and zolpidem an α_1 -subunit-preferring full positive modulator [106]. Therefore, competitive binding assay results need to be complemented with data on the intrinsic efficacies of the compounds before making any behaviorally relevant predictions. Even in the case that both data sets are available, behavioral effects may be due to receptor populations that cannot be mimicked in vitro. This has been seen, for example, in the granule cells of the cerebellum: Though the array of subunits is restricted to α_1 , α_6 , β_2 , β_3 , and δ , only 50% of the pharmacology seen in rat brain slices could be accounted for by any of possible subunit combinations in vitro [107]. The same issue becomes important when one attempts to apply in vitro selectivity data into human brain imaging studies with the purpose of visualizing various subtypes of GABA_A receptor.

Exchanging the β subunit in ternary $\alpha_i\beta_f\gamma_2$ receptors did not significantly alter the BZ binding characteristics [108, 109] for flunitrazepam, DMCM, FG8205, zolpidem, or CL 218,872 between the β_1 , β_2 , and β_3 isoforms in electrophysiological recordings [109]. Accordingly, Puia [110] reported for diazepam or bretazenil only a tendency toward a decreased potentiation while exchanging β_1 with the β_2 or the β_3 subunit in $\alpha_i\beta_f\gamma_2$ receptors. Sigel, however, observed a severalfold higher potentiation in $\alpha_{1/3}\beta_2\gamma_2$ receptors, as compared to $\alpha_{1/3/5}\beta_1\gamma_2$ [111]. The minor relevance of the β subunits in ternary receptors to BZ pharmacology was also seen when studied by [³⁵S]TBPS binding, although, in $\alpha_5\beta_f\gamma_{2/3}$ and to a lesser extent in $\alpha_3\beta_f\gamma_{2/3}$ receptors, the β_3 variant was required for high-affinity [³⁵S]TBPS binding [101, 104]. Interestingly, this correlates with the notion that α_5 -subunit mRNA colocalizes with β_3 mRNA [112, 113]. Another study on homo-oligomeric β_3 channels reported this subunit to be sufficient for high-affinity [³⁵S]TBPS binding [114].

The receptor structures are further altered by posttranslational modifications, but the roles of these processes in function and in pharmacological specificity have not been well established. The receptor subunits show sequence similarity of about 70% within classes and about 30% between classes.

3.3.2 Functional Domains

3.3.2.1 GABA and BZ Binding Pocket. Addition of the neurotransmitter triggers a small rotation of the extracellular domains of the receptor subunits [115], which then opens the channel pore formed by the adjoining transmembrane 2 TM2 regions of the five subunits as predicted from the data obtained with nicotinic acetylcholine receptors [116]. Using disulfide bond mapping in recombinant GABA_A $\alpha_1\beta_1$ mutant receptors, Horenstein et al. [117] demonstrated that the extracellular portion of the TM2-lined pore is more flexible than the intracellular portion and that these domains of the α_1 and β_1 subunits rotate asymmetrically, since homologous residues (α_1 T261C and β_1 T256C) form disulfide bonds only when the receptors are activated by GABA. The resulting covalent modification keeps the channels open.

The physical pore properties of GABA_A receptors are remarkably invariant among different subunit compositions (see [118]). Still, different compounds exert their action on the receptor via a range of different modes. For example, pentobarbital increases the mean duration of opening time and the mean number of openings per burst [119], but, as described before, BZ-positive modulators increase the open frequency [119] and BZ-negative modulators decrease it. Furthermore, though picrotoxinin does not directly interact with the binding site for pentobarbital, it produces the opposite effects on the receptor; that is, it reduces the mean number of openings per burst and shortens the mean open time [119]. Picrotoxinin protects the covalent modification of an α_1 V257C substitution by a sulfhydryl reagent in the intracellular portion of the TM2 region [120], possibly because of a direct steric hindrance by picrotoxinin, suggesting the direct blockade of the channel pore by ligands of this type.

The minimal structural requirement for GABA_A receptors gated by GABA is a heteropentamer built from two different subunits with one peptide derived from the α class and the other from the β class of variants [121]. Thus, it was expected that both subunit classes contribute to the formation of the GABA binding pocket. Indeed, a number of amino acids on members of both classes, most of them conserved within a subunit class, have been identified as being involved in high-affinity agonist binding. The first one in this series was recognized by the F-to-L mutation at position 64 in the rat α_1 subunit in an electrophysiological assay [111, 122], later confirmed by direct photolabeling of the site with [³H]muscimol [123]. Whereas the homologous residue in the α_5 variant was shown to be involved in the formation of the GABA binding pocket, the equivalent residues in the β_2 and γ_2 subunits do not affect GABA binding [122]. The two neighboring amino acids R66, corresponding to R70 in α_5 , and S68 in the α_1 variant have been reported to contribute to the GABA binding domain [124, 125], as well as R120 in α_1 and its counterpart R123 in α_5 [125, 126].

[³H]RO 15-4513 (Fig. 3.3) binding to BZ sites is differently modulated by GABA in various recombinant receptors. In $\alpha_1\beta_2\gamma_2$ receptors, GABA reduces its binding, which is in agreement with the classification of RO 15-4513 as a negative modulator [127]. In the $\alpha_6\beta_2\gamma_2$ receptors, GABA enhances significantly the binding. [³H]RO 15-4513 binding is sensitive to diazepam in $\alpha_1\beta_2\gamma_2$ ($K_i = 16$ nM [128]) and $\alpha_6(Q100)\beta_2\gamma_2$ ($K_i = 1.3$ μ M [129]) receptors but insensitive in $\alpha_6\beta_2\gamma_2$ receptors. These actions are also consistent with electrophysiological results ([130, 131], but see [132]), demonstrating that negative modulators act like positive modulators at $\alpha_6\beta_x\gamma_2$ and $\alpha_4\beta_x\gamma_2$ receptors. The observation that the intrinsic activities of flumazenil, ranging from

antagonistic to partial positive modulatory, and RO 15-4513, ranging from partial negative modulatory to partial positive modulatory, depended on the amino acid replacing the H101 [133] supports the idea that the amino acid at this position affects the intramolecular transduction of an allosteric effect and not only the ligand binding domain structure.

In the years after cloning the first GABA_A receptor subunit complementary DNAs (cDNAs) site-directed mutagenesis has contributed to the identification of residues on single subunits in a receptor complex involved in specificity, selectivity, and efficacy differences of BZ receptor ligands. In many cases the approach proceeded over the construction of chimeric proteins derived from two subunits with largely differing properties to finally point to a single amino acid. Another possible procedure employed the high sequence identity between subunits of a given class to directly point to amino acid candidates explaining physiological and pharmacological differences between GABA_A receptors. The first approach was used to largely explain the molecular basis of the so-called BZ type I and type II receptors. An E is conserved in all α variants at the position 201 besides in α_1 . Its exchange by a G leads to an increase in the affinity for the α_1 -preferring compounds CL 218,872 and 2-oxo-quazepam [134]. Further identified amino acids are T208 and I215 of the human α_5 subunit which confer high subtype selectivity of the partial inverse agonist L-655,708 to $\alpha_5\beta\gamma_2$ receptors in α_5 (T208S, I215V) $\beta_1\gamma_2$ receptors [135], the homologous residues affecting also the affinity of zolpidem in α_1 (S208T, V215I) $\beta_1\gamma_2$ receptors. However, these residues only slightly reduced the affinity of CL 218,872 binding. Still, these effects stress the importance of the whole domain between amino acid residues 201 and 215 in BZ binding [136, 137].

One of the most instrumental amino acid residues in the elucidation of BZ pharmacology is the H (in α_1 , α_2 , α_3 , and α_5) to R (in α_4 and α_6) transition at a position corresponding to R100 in α_6 . The single R-to-H substitution at positions 99 of α_4 and 100 of α_6 imparts sensitivity of these receptors to diazepam [137, 138]. Furthermore, diazepam insensitivity can be conferred to α_1 receptors by replacing the corresponding H101 with an R [138]. The point mutation only changes the affinity for diazepam but does not interfere with the affinity for GABA [139], a fact that has been utilized to dissect the behavioral pharmacological actions of classical BZs such as diazepam and at least partially attribute their diverse actions on receptors containing individual α subunits (see below). As well, diazepam-insensitive $\alpha_6\beta_2\gamma_2$ receptors can be converted to a diazepam-preferring species by four amino acid exchanges in the α_6 variant, thus reversing the rank order of potency of BZ receptor ligands in mutated as compared to wild-type receptors [137].

As briefly noted before, the same amino acid residue in the α_6 subunit has been identified as being polymorphic in rats: Alcohol-insensitive (AT) and alcohol-sensitive (ANT) rat lines were developed by selective outbreeding for differential sensitivity to the motor-impairing effects of an acutely administered moderate dose of ethanol (2 g/kg) [140]. The motor impairment was measured with a tilting plane test on a rough surface [141], which evaluates quick postural adaptations, supposedly needed cerebellar adjustment. The ANT rats are abnormally BZ agonist sensitive and have also slightly greater sensitivity to the motor-impairing actions of barbiturates, intravenous anesthetics, *N*-methyl-D-aspartate receptor antagonists, and neurosteroid agonists [142–145]. There are no overall differences in brain GABA_A receptors between the ANT and AT rat lines [146, 147], but the binding of [³H]RO 15-4513 to

the cerebellum in ANT rats is about 100-fold more sensitive to diazepam and lorazepam than the binding in AT rat samples [148, 149], resulting in reduced “diazepam-insensitive” BZ binding in ANT rats. This is caused by a single nucleotide exchange in the GABA_A receptor granule cell-specific α_6 subunit gene in the ANT rats leading to an R-to-Q exchange [150]. Interestingly, even if ANT rats differ from AT rats only in their cerebellar granule cell sensitivity to diazepam, in behavioral tests for the anxiolytic activity of diazepam they show heightened responses as compared to AT rats [151], suggesting that the cerebellum is also important for emotional behavior. Interestingly, the highly alcohol sensitive ANT rats consume voluntarily less alcohol than the alcohol-insensitive AT rats [152]. In proof, Saba et al. [153] have recently described a Sardinian alcohol-nonpreferring rat line to spontaneously have exactly the same mutation as the ANT rats in the α_6 subunit. However, whether these presumably α_6 -subunit-mediated effects of alcohol are due to receptors containing the γ_2 subunit and have to be thus classified as GABA_A/BZ receptors have still to be evaluated, especially in light of the more recent publication of the high sensitivity of $\alpha_6\beta_3\delta$ receptors against ethanol [154].

As outlined before, all GABA_A receptors of the composition $\alpha_i\beta_j\gamma_k$ ($i = 1, \dots, 6$, $j = 1, \dots, 3$, $k = 2, 3$) are BZ sensitive. Thus, it was only a question of time before the γ_2 subunit was molecularly dissected to identify amino acids crucial in BZ pharmacology. In this line, a single amino acid residue has been identified in the γ_2 subunit, which seems to critically determine the efficacy of a given BZ receptor ligand with a GABA_A receptor subtype [155]. If T142 in γ_2 is converted to serine, the channel response of the resulting $\alpha_1\beta_1\gamma_2$ receptor to 5 μ M GABA is increased by flumazenil and RO 15-4513 (instead of being unaffected or decreased in the corresponding wild-type receptors), thus converting negative or neutral allosteric modulators into positive ones. The F at position 77 of the γ_2 subunit is homologous to the above-mentioned F64 in the α_1 and α_6 subunits. Whereas the latter is required for high-affinity GABA functionality, the former is involved in high-affinity binding of several BZ receptor ligands, for example, zolpidem, the β -carboline DMCM, diazepam, and CI 218,872 [136, 156]. A similar correspondence between GABA and BZ responsiveness was found for amino acids involved in the GABA recognition on the β subunit [157] and BZ binding site on the homologous α -subunit residues [158]. Both findings substantiate the claim that the BZ binding site is a “converted” agonist recognition site.

Recently, two domains in the γ_2 subunit have been identified as transducing elements for the BZ activity, one being in the region TM1, the other in the adjacent region TM2 including the following short extracellular loop [159]. Together these domains may form the structural basis for the enhancement of GABA-induced currents by BZ receptor ligands.

For some BZ site ligands, such as β -carbolines, an additional binding site on GABA_A receptors independent of γ_2 subunits has been suggested [160, 161]. In addition to the function as a negative modulator on the BZ site at low micromolar concentrations, DMCM, ethyl- β -carboline-3-carboxylate (β -CCE), and propyl- β -carboline-3-carboxylate (β -CCP) at high micromolar concentrations potentiate the GABA_A receptor function through a supposedly loreclezole-associated binding site in the β_2 and β_3 subunits [162]. This positive modulatory effect is independent of the α variant present in the receptor complex and is more pronounced in α_6 -containing receptors due to the lack of inhibition (negative modulation) by the BZ binding site

[160, 161]. This site can be detected especially in the cerebellar granule cell layer by using [^{35}S]TBPS autoradiography, and it is decreased in the absence of α_6 subunits [163] but retained in $\gamma_2(\text{F77I})$ point-mutated mice [164], which show absence of DMCM-induced convulsions and presence of DMCM-induced motor impairment. As the effects are insensitive to flumazenil, they cannot be classified as being BZ receptor mediated though they are due to long known BZ receptor ligands.

An additional low-affinity BZ site has been suggested based on receptor assays in frog oocytes [165]. Diazepam, flunitrazepam, and midazolam but not flurazepam at micromolar concentrations produced strong enhancement of currents induced by a low GABA effective concentration (EC_3 sic!) in $\alpha_1\beta_2\gamma_2$ as well as $\alpha_1\beta_2$ receptors. In line with the subunit restrictions given before, nanomolar concentrations of all tested BZ agonists enhanced GABA responses in $\alpha_1\beta_2\gamma_2$ receptors, but to a lower extent than the micromolar concentrations of the active ones in γ_2 -less receptors. Importantly, only the nanomolar actions were blocked by the selective antagonist flumazenil. It remains to be shown in vivo whether these effects have any functional role, the simple test being the demonstration of flumazenil-insensitive sedation or anesthesia by the above-mentioned active BZs.

3.3.2.2 Assembly, Clustering, and Surface Expression. Most but not all GABA_A receptors assemble as *heteropentamers* and require signaling sequences for the specific interaction of the subunits. One of the sequences was identified employing a natural splice variant of the α_6 subunit which is alternatively spliced in about 20% of its transcripts in rat brain, causing a 10-amino-acid deletion of the amino acids E57 up to Q66, thus including the residues F and R, positions 63/65 and 64/66 in α_6 and α_1 , respectively [166]. When this spliced α_6 subunit is expressed in HEK 293 cells together with β_2 and γ_2 subunits, no binding activity of GABA or any BZ ligand is detected. Similarly, when the same subunits are expressed in *Xenopus* oocytes, no GABA-responsive channels are formed, though the transcript is translated in vitro. On a first glance, this result corroborates the idea that the GABA and/or BZ binding domains are at least partly in the extracellular region of the α subunits. Taylor et al. [167] have, however, shown that the short alternatively spliced α_6 subunit does not assemble into receptors that reach the plasma membrane, indicating that the deleted domain or a subsequent tertiary structural alteration affects membrane targeting. A stretch of 70 amino acids in the second half of the N-terminal extracellular domain was identified to be important for the homo-oligomeric assembly of the GABA_C receptor ρ_1 but not the ρ_2 subunits [168]. In rat α_1 and γ_2 subunits, domains have been detected [$\alpha_1(80-100)$ and $\gamma_2(91-104)$] that are necessary for subunit interaction, assembly, and formation of BZ binding site [169, 170] in recombinant $\alpha_1\beta_3\gamma_2$ receptors. Another adjacent region of the γ_2 subunit [$\gamma_2(83-93)$] might be needed for interaction with β_3 subunits [170].

Recently, a glia-derived protein was identified in the CNS of the mollusk *Lymnaea* [171]. This protein binds acetylcholine, shows a 15% sequence identity to the N-termini of nicotinic acetylcholine receptor subunits at domains that are suggested to be important in the formation of the agonist binding sites, and contains a cysteine loop with 12 (instead of 13) intervening amino acids. It lacks the membrane-spanning domains, thus forming soluble (i.e., non-membrane-bound), *homopentameric* complexes [172]. This stresses the importance of the extracellular N-terminus for the assembly of subunits in this family of ligand-gated ion channels. Importantly, there

are already data to suggest that at least BZ binding sites can be formed by truncated N-terminal extracellular domains in GABA_A receptor α_1 - and γ_2 -subunit dimers, whereas [³H]muscimol binding apparently requires also transmembrane domains of the α_1 subunits together with truncated β_3 subunits [170].

The altered pharmacology of native GABA_A receptors and changes in the γ_2 - and α_4 -subunit levels in δ -subunit-deficient mice indicate that the δ subunit preferentially assembles in the forebrain with α_4 subunits, where it interferes with the coassembly of α_4 and γ_2 subunits, the γ_2 subunit being recruited into additional functional receptors in its absence. This provokes the question of how GABA_A receptor subunit assembly is regulated in the normal brain. Little further is known besides that the N-terminal domains of the α subunits are obligatory for this process [167, 173], elegantly proven by the assembly of the homopentameric acetylcholine binding protein of *Lymnaea* [172]. Two scenarios exist to explain these results, that is, either the concentration of δ subunit exceeds that of the γ_2 subunit or the δ subunit has a higher probability than the γ_2 subunit in assembling with α_4 and α_6 subunits. In both scenarios, δ and γ_2 subunits compete with each other during assembly into functional receptors in neurons, a process which could efficiently limit the number of receptor subtypes, that is, subunit combinations, produced and especially the number of BZ-responsive GABA_A receptors. However, recombinant $\alpha_4\beta_3\gamma_2\delta$ GABA_A receptors are formed in HEK 293 cells [174] where the γ_2 and δ subunits assemble into functional receptors as demonstrated by their selective electrophysiological and pharmacological properties, though at a reduced expression level. However, fibroblasts may lack molecular features such as clustering proteins [175–177] that might be needed for the selective assembly or ideal function of subunits in vivo, thus further enlarging the once-thought narrow gap between the in vitro and in vivo properties of GABA_A receptors.

The γ_2 and γ_3 subunits not only confer BZ sensitivity to the resulting GABA_A receptors but also are instrumental in the subcellular targeting of the receptors, that is, the clustering of the receptors and/or the synaptic versus the extrasynaptic location of the receptors. Two main players have been identified to be involved in these cellular processes, gephyrin and GABA_A receptor-associated protein (GABARAP). In the following we will briefly outline their properties. Gephyrin, initially described as a 93-kDa protein copurified with glycine receptors [178], is now known to be more widely expressed in the CNS as well as peripheral tissue, even in areas devoid of the glycine receptor [179]. Mice lacking gephyrin die at day 1 after birth (P1) and exhibit a reduced number of clustered glycine receptors at their synapses but not an overall loss of glycine receptors [180]. As well, a significant reduction in the punctuate immunoreactivity toward the GABA_A receptor α_2 and γ_2 subunits is observed in spinal cord sections of these mice [181]. In primary hippocampal neuronal cultures synaptically clustered GABA_A receptors are reduced but their intracellular pool is increased. Together with results from γ_2 knockout mice, which exhibit a loss of clustered GABA_A receptors [182, 183], these data provide evidence for a dominant role for gephyrin and probably the $\gamma_{2/3}$ subunits in GABA_A/BZ receptor clustering. The pool of GABA_A receptors clustered extrasynaptically, as detected by $\beta_{2/3}$ - and γ_2 -specific antibodies in wild-type hippocampal neurons, is reduced during development, but even after 30 days in culture it amounts to 50% of all clusters [184]. This leaves open the question on the mode of specific targeting of these clusters or the precise subunit composition of extrasynaptic versus synaptic clusters.

Employing the yeast two-hybrid system, a ubiquitously expressed protein was identified to interact with a part of the large intracellular loop of the γ_2 subunit [185]. In spite of its distribution pattern it was called GABARAP. It exhibits sequence similarity with light chain 3 of microtubule-associated proteins and a putative tubulin binding motif, which apparently directly interact with microtubules and tubulin, respectively [186]. Recombinant $\alpha_1\beta_2\gamma_{2L}$ receptors expressed together with GABARAP have variable GABA sensitivity and channel kinetics depending on whether the receptors are in clusters or diffusely distributed on the cell membrane [175]. Using again the technique of yeast two-hybrid screening, Kanematsu et al. [187] found an inositol 1,4,5-trisphosphate binding protein, called p130, that may bind to GABARAP and inhibit the binding of γ_2 subunit to GABARAP. The p130 knockout mice show reduced sensitivity to diazepam in both behavioral and hippocampal electrophysiological experiments, whereas GABA-induced receptor currents are unaltered. The roles of the GABARAP and p130 are still unresolved, especially as the GABARAP-deficient mouse line appears to have no defects in GABA_A receptor membrane targeting [188].

Insertion of proteins into the plasma membrane and the half time of surface expression represent a highly regulated process. Thus, it is not really astonishing that there are proteins regulating these processes. In this line the ubiquitin-like protein Plc-1 has been found to interact with several α and β subunits of the GABA_A receptor [189]. This protein seems to be important for facilitation of GABA_A receptor surface expression and intracellular stabilization of subunits. Recently, it was shown that GABA_A receptors are constitutively internalized by clathrin-dependent endocytosis [190], which could be traced to the interaction of β and γ_2 subunits with the adaptin complex AP2. This interaction may be functionally important in vivo as the blockade of endocytosis increased the amplitude of GABA-induced miniature inhibitory postsynaptic currents in hippocampal neurons by two. The internalization of the $\alpha_1\beta_2$ and $\alpha_1\beta_2\gamma_2$ receptors in HEK 293 cells is strongly modulated by phosphorylation/dephosphorylation reactions [191], but the modulations might not be GABA_A receptor specific. Especially, the role of protein kinase C-mediated phosphorylation of receptor interacting proteins needs to be assessed. The functional and pharmacological regulation of receptor surface expression, subunit stabilization, and internalization thus remain to be studied, but the present scarce data already suggest that these mechanisms may also vary between different GABA_A receptor subtypes [192].

Whether the factors described here contribute to the mentioned discrepancy between the observed in vitro and in vivo effects of BZ receptor ligands will be a major focus of BZ research. Further, they might be important for the receptor regulation during tolerance development. Even more so, the results may even point to future pharmacological targets to treat disorders currently medicated with BZ receptor ligands.

3.3.3 Diversity of Brain Distribution

Early autoradiographic experiments have shown GABA_A receptor-associated GABA site labeling using [³H]muscimol as a ligand [193]. More thorough examination, however, has raised the suspicion that the high-affinity binding of GABA site ligands does not distribute as widely in the CNS as BZ site or channel site ligands labeled by [³H]BZ and [³⁵S]TBPS, respectively. The GABA binding site as seen with [³H]muscimol is concentrated especially to the cerebellar granule cell layer and thalamus, whereas the diencephalon and colliculi are hardly labeled contrasting with

the labeling patterns by [³H]BZ and [³⁵S]TBPS. Thus, [³H]muscimol autoradiographies indicate that GABA site labeling reveals only a fraction of all GABA_A receptors, though it is the prototypic agonist acting on all GABA_A receptor subtypes in functional assays at high nanomolar–low micromolar concentrations. High-affinity [³H]muscimol binding to rat brain sections was proposed to be associated with δ -containing receptors [194, 195]. This was corroborated by the findings that [³H]muscimol binding to GABA sites is reduced in cerebellar sections from α_6 knockout mice [163] exhibiting a reduced number of α_6 - and/or δ -subunit-containing receptors [196] and that in δ -deficient mice [197] the high-affinity [³H]muscimol binding is reduced in both the cerebellum and forebrain [145]. In contrast, [³H]RO 15-4513 binding to BZ sites of the cerebellum and forebrain is increased in $\delta^{-/-}$ animals, which was, at least partly, due to an increase in diazepam-insensitive receptors. Concurrently the amount of the γ_2 subunit, as determined by Western blotting, is increased and that of α_4 decreased in $\delta^{-/-}$ animals, while the level of the α_1 subunit remains unchanged [145], indicating augmented assembly of γ_2 subunits with α_6 and α_4 subunits in the absence of the δ subunit. This points to an increased expression of BZ receptors as a compensation to the decrease of high-affinity GABA recognition sites [128, 198, 199].

As stated before, GABA_A receptors responsive to BZ receptor ligands require any α variant together with any β subunit and either γ_2 or γ_3 . In these configurations the β subunits are known to contribute little to the differences in the BZ ligand-mediated effects and the γ_3 subunit is rare (see below). Therefore, mainly the α subunits determine the pharmacological and physiological responses of GABA_A receptors to BZ receptor ligands. Thus, the following description focuses on the α_1 variant distribution in the CNS, especially as the γ_2 subunit is found in nearly all brain regions, though to different intensities [200].

The α_1 subunit appears to be the most abundant subunit in the CNS, missing only in a few regions and often colocalizing with the β_2 subunit [112, 113, 201–203]. Strong α_2 - and α_3 -subunit expression seems to inversely correlate with α_1 expression. These two subunits as well as α_3 and α_5 are abundant in the hippocampus [113, 202]. The $\alpha_3\beta_1\gamma_2$ -subunit combination is reported for serotonergic neurons of the raphe nuclei and cholinergic neurons of the basal forebrain [204–206]. Some subunits dominate during embryonic development, for example, α_2 , α_3 , and α_5 [202, 207, 208], but are reduced or even absent in defined regions in the adult brain [209]. The time-delimited presence of specific subunits during ontogenesis in defined brain regions appears to be essential for normal development [210, 211]. Other neurons, for example, the cerebellar Purkinje cells, maintain their subunit composition of $\alpha_1\beta_{2/3}\gamma_2$ throughout all pre- and postnatal stages [202]. It is also possible that more than one α subunit is in a pentameric complex [212, 213].

The α_5 subunit, concentrated in the adult hippocampus and olfactory bulb [113, 214], is part of a receptor with negligible affinity for BZ receptor ligands such as the imidazopyridine zolpidem [103, 215] (see Fig. 3.4). Major amounts of the α_4 subunit are found in the hippocampus and thalamus and often colocalize with the δ subunit [198]. The α_6 subunit, also found to colocalize with the δ subunit, appears to be almost exclusively restricted to the cerebellar granule cells [128] with some traces found in the dorsal cochlear nucleus [216, 217], a brain area developmentally derived from cerebellar precursors.

The β_1 mRNA signals are strongest in the hippocampus, less pronounced in the claustrum and parts of the stria terminale, and weak in the amygdala and

hypothalamus [113, 218, 219], whereas the β_2 subunit shows more widespread distribution that seems to be inversely correlated to the β_1 and β_3 concentrations, for example, in the hypothalamus and in parts of the hippocampus [113, 218, 219]. Here the β_3 subunit is strong, mainly in CA1 and CA2, but as well in the olfactory bulb, cortex, caudate putamen, nucleus accumbens, and hypothalamus. Like for the α variants, studies on the distribution of the β_1 , β_2 , and β_3 subunits during pre- and postnatal ontogeny indicate an independent regulation of their expression in different brain regions that suggests a role during development [202, 209, 220]. A line of proof is a mouse line devoid of the chromosomal region encoding α_5 and β_3 that bears a neonatally lethal cleft palate [221]. Introduction of a transgene coding for the β_3 subunit rescued these mice [211], thus proving not only the responsibility of β_3 for the cleft palate but also the role of the β_3 variant in development, in this specific case outside the CNS. These observations provoke the question of whether BZ can cause congenital malformations. Indeed, there have been early reports to this end [222, 223], which, however, could not be substantiated in more recent studies [224, 225].

The ubiquitous presence of the γ_2 subunit and hence the BZ receptor is contrasted by the restricted distribution of the γ_1 and γ_3 variants. Messenger RNA encoding the γ_1 subunit is limited to regions of the amygdala, septum, and hypothalamus [226]; the γ_3 subunit is largely present in the olfactory bulb, cortex, basal nuclei, and medial geniculate of the thalamus [99, 113, 227].

Immunoprecipitation studies with an α_6 antibody suggested that between 10 and 40% α_6 subunit is combined with the α_1 subunit [212, 228]. Caruncho and Costa [228a], however, concluded from double immunolabelings of freeze-fracture replicas that these two subunits do not colocalize within the same receptor complex. Based on mRNA and protein colocalization, further subunit combinations containing more than one α variant have been suggested, such as $\alpha_1\alpha_3\beta_{2/3}\gamma_2$ [203, 213, 229]. However, immunoprecipitation studies might include incompletely assembled receptors as well as receptors not inserted into the outer cell membrane [192]. As well some receptor pools might be underestimated in such studies because they are not readily solubilized by conventional detergent treatments [230].

In addition to the differences between [^3H]BZ and [^3H]muscimol binding distribution, there exists a large discrepancy between the high-affinity [^3H]GABA site ligand binding to brain sections, membrane homogenates, or recombinant receptor preparations on one side and the low-affinity binding of these ligands suggested from allosteric actions in functional assays employing electrophysiological methods and [^{35}S]TBPS and [^3H]BZ binding assays on the other side. Whereas the former is uniformly in the range of tens of nanomolar [104], the latter varies from high nanomolar to the micromolar range [101, 118, 231]. As this discrepancy holds true for single-receptor preparations, it cannot be due to receptor heterogeneity but rather must be an intrinsic receptor property. One likely explanation is the interconversion between a low-affinity and a high-affinity state, which, however, still awaits a definite biochemical proof.

3.3.4 BZ Functional Diversity as Revealed by Gene Knockout and Knockin Models

The most dramatic increase in knowledge about the functional diversity of BZ receptor ligands has been obtained in the past years by the use of knockout models and even more pronounced by mouse knockin models for GABA_A/BZ receptors.

These studies revealed that the deficiency of some subunits such as the GABA_A receptor γ_2 and the before-mentioned β_3 subunit cannot be compensated for in the developing brain. Mouse lines devoid of these subunits are severely compromised [210, 232], and thus absence of these subunits is incompatible with life, at least during development.

The α_5 -subunit gene, the expression of which is largely restricted to the hippocampus but as well present in parts of the cortex and more widespread in prenatal development, has been disrupted in mice and their behavior has been analyzed. They show enhanced platform learning in the Morris water maze and normal behavior and normal sensitivity to BZ agonists in the elevated-plus maze test of anxiety [233]. It is thus possible that inhibition of α_5 -subunit-containing receptors might help in improving cognitive functions, though the basic function of this subunit can obviously not be to curtail learning ability. A more philosophical aspect is the idea that forgetting is as essential for life as learning. Interestingly, as mentioned above, reduction of the expression of this subunit in the hippocampus seems to correlate with tolerance development to prolonged BZ treatment in animal models [75, 76].

The lack of γ_3 , α_6 , and δ subunits, and even in view of the data cited above, the lack of the α_5 variant does not produce any strong behavioral or physiological phenotype [197, 233–237]. Even more surprisingly, the homozygotic loss of α_1 or β_2 subunits resulting in a 50% reduction of all GABA_A receptors [238] is associated with neither lethal or strong behavioral effects, indicating functional compensation. However, though a general increase in other α -subunit expressions would be expected in these mice, the contrary was found: The α_6 -subunit-dependent BZ-positive modulator-insensitive [³H]RO 15-4513 binding is reduced by about 30%, suggesting that proper assembly or membrane targeting of the α_6 subunits needs the presence of α_1 subunits [238]. More recent experiments on the α_1 knockout mice have revealed clear compensations, especially by increased α_2 and α_3 subunits in the forebrain [239].

The proposal that the α_6 subunit plays a significant role in the action of alcohol [240] warranted an analysis of the behavior of α_6 -subunit-deficient mice behavior in response to sedative compounds [235, 236]. Two independently generated α_6 knockout lines lack the subunit-specific [³H]RO 15-4513 binding in the cerebellar granule cell layer but neither exhibit any immediately apparent motor learning or coordination deficits nor is their alcohol and anesthetic sensitivity different from that of wild-type animals [241]. However, their motor function is more readily affected by diazepam than that of the wild-type mice [242]. A potassium leak current carried via the Task-1 channel is increased in $\alpha_6^{-/-}$ mice, most likely needed to counteract the loss of inhibition in the cerebellar granule cells [243]. Analogous phenomena similar to this may occur in all other GABA_A knockout mice, obscuring the biological significance of the subunits and hindering the interpretation of the lack of apparent behavioral consequences.

To overcome these obstacles, Rudolph, Möhler, and co-workers as well as Rosahl, Whiting, and co-workers utilized a gene knockin approach that alters the diazepam-sensitive sites in α_1 -, α_2 -, α_3 -, and α_5 -subunit-containing receptors into insensitive ones by exchanging the H to R at the position N-terminal to the cysteine loop that is crucial for diazepam sensitivity [138]. These mouse models produced information on the behavioral roles of GABA_A receptor subtypes. Initially, this approach was thought to provide the final answers to the GABA_A receptor subtype-specific actions of BZ receptor ligands. In the first round of experiments two groups independently

reported that in α_1 (H101R) mutant mice diazepam is no longer sedative and amnestic, partially lost its anticonvulsant effects, but retained normal anxiolytic properties [244, 245]. However, α_1 (H101R) mice react normally to diazepam with respect to sleep-related parameters [246]; most like hypnotic sleep-related effects most likely involve other GABA_A receptor subtypes.

The α_2 (H101R) mice, that is, mice with a BZ-insensitive α_2 variant, did not display clear anxiolytic responses to diazepam, while their sedative responses to BZs were normal [247]. This is not surprising in view of the involvement of a number of brain regions in anxiety-related behavior, including the amygdala, a structure with high α_2 content, mammillary bodies, and dorsal hippocampus (see [113, 248]). More recent data, however, put into question the involvement of solely the α_2 subunit in the anxiolytic effects of BZ receptor ligands. Along this line, α_3 -containing receptors may mediate anxiolytic effects of novel subtype-selective BZ ligands [249, 250]. Interestingly, the α_3 (H126R) mice showed no deficits in the actions of diazepam [251], though the α_3 subunit is strategically expressed in important monoaminergic nuclei [203] believed to be involved in the regulation of emotional behavior. As well, even α_5 -containing receptors cannot be totally excluded to be involved in anxiety behavior [252]. Further experiments with these models will be important to exclude compensatory alterations in the GABAergic or other systems which may occur in spite of the absence of any proven endogenous BZ receptor ligands (see above) and in the absence of any overt physiological changes in GABA sensitivity of the mutated α variants. As well, the roles of these subtypes in behaviors such as tolerance and dependence to BZs need to be clarified. The muscle-relaxing effects of BZ receptor ligands seem to be largely mediated by the α_2 subunit as in the BZ-insensitive α_2 variant mice the myorelaxant action of diazepam was almost completely abolished [251].

As well, the role of the α_5 variant in the action of BZ receptor ligands did not become as clear as hoped for when mice carrying the H-to-R mutation were analyzed [253]: Diazepam no longer exerted the full muscle-relaxing effect seen with high doses of BZ ligands, but the sedative, anticonvulsant, and anxiolytic effects of diazepam were unaffected in these mutant mice. Surprisingly, the point mutation resulted in a selective reduction of α_5 -containing GABA_A receptors in hippocampal pyramidal cells resulting in an overall loss of 20% of the α_5 protein, which in itself did not change the above-mentioned effects but changed the response in a trace fear-conditioning task in which a tone associated with an electric shock was separated by an empty time interval independent of any external BZ. Though these results can be taken as a hint for the involvement of the α_5 subunit in some type(s) of associative learning, the role of BZ receptor ligands is still open for discussion. The same mutant mice did not develop any tolerance to the α_1 -mediated sedative effects of diazepam which was interpreted as a regulatory crosstalk between two GABA_A receptor subtypes [75].

3.4 STRUCTURE ACTIVITY RELATION OF BENZODIAZEPINES

In a strict sense all BZ receptor ligands are GABA_AR subtype selective as none of these ligands recognizes all native or heterologously expressed ligand-gated ion channels of this type, simply because, contrary to previous beliefs, not all GABA_AR

are BZ receptors. Slightly more relevant to the pharmacology of BZ receptor ligands is the observation that not a single ligand in clinical use binds to all BZ receptors with similar affinity, simply because no BZ receptor ligand recognizes GABA_A/BZ receptors containing the α_4 or α_6 subunits, resulting in the term “diazepam-insensitive” (DI) BZ receptors for $\alpha_{4/6}\beta_f\gamma_2$ receptors. However, these receptors bind the azido derivative of flumazenil, RO 15-4513, with high affinity that is identical to all receptors of the configuration $\alpha_i\beta_f\gamma_2$ ($i = 1, \dots, 4, 6$; $j = 1, 2, \dots, 3$) and this ligand binds to α_5 -containing BZ receptors with an even 10-fold higher affinity. Still, this selectivity does not play any role in clinical practice, whereas compounds which selectively recognize any given receptor of the types $\alpha_i\beta_f\gamma_2$ ($i = 1, 2, 3, 5$ with any $j = 1, 2, 3$) would be highly desirable.

Two different strategies have been employed to probe the structural requirements of BZ receptor ligands with specific receptor subtypes. One might be called the “molecular path,” in which putative subtype-selective compounds are tested on an array of recombinant receptor subunit combinations with biochemical and/or electrophysiological methods. The second one assumes that certain aspects of pharmacological BZ receptor ligand effects are mediated through defined receptor subpopulations and might be called the “behavioral path.” A third possible route has not yet been taken and presumably it will take some time before it will lead to a successful end in the field of the BZ receptor ligands. It takes advantage of structural data of the receptor to fit appropriate molecules directly into the pharmacophore. Especially the latter but also the first route is hampered by the continuum of effect size of these BZ receptor ligands from full negative modulators up to full positive modulators, though, on the other hand, this range of effect size has facilitated the development of so-called functional selective compounds, in which the given compound binds to some or all receptor subtypes but the efficacy is, at best, zero on one type and 100% on the other.

As far back as 1993, intrinsic efficacy differences were supported to mediate the differing effects of BZ receptor ligands [254], although the molecular diversity of GABA_A/BZ receptors was traced to the existence of several α variants already in 1989 [108]. A fuller appreciation to its now-known extent came in the following years [103, 128, 198], although BZ type I over BZ type II preferring compounds like CL 218,872, quazepam, and 2-oxo-quazepam were identified over 20 years ago [255–258]. The first subtype-specific structure–activity analysis was made under the assumption that in the cerebellum [³H]flunitrazepam binding represents a single receptor population [259], an assumption we now know to be essentially but not totally correct as only 90% of all diazepam-sensitive receptors in this brain region contain the α_1 variant and thus represent the BZ type I receptors. Zolpidem is now the most subtype-selective BZ receptor ligand in clinical use. It displays a 12- to 25-fold higher affinity to α_1 -containing receptors as to α_2 - and α_3 -containing receptors, paired with negligible affinity to all other α variant receptors [103, 260]. Recently, a zolpidem derivative was shown to be even more α_1 selective than zolpidem: This compound only recognizes the most abundant $\alpha_1\beta_f\gamma_2$ receptors [261] but still displays anxiolytic-like properties.

It took a few more years before the first molecular modeling approaches were performed in the search for α -subunit-preferring compounds with a single receptor population [262, 263], in this specific case, the α_6 -containing and thus one of the two theoretically possible diazepam-insensitive receptors. By analyzing close to 50 BZs

[263], the authors concluded that the ester substituent and substitutions at position 6 besides the obvious position 7 of imidazo-[1,4]benzodiazepines (compare Fig. 3.3) have a marked influence on the ratio of affinity for diazepam-sensitive to diazepam-insensitive receptor subtypes. However, no ligand was identified that had a substantially higher affinity to α_6 -containing receptors or a ratio of affinities substantially in favor of α_6 -containing receptors.

More comprehensive pharmacophore models were proposed in the following years and included not only the α_6 -containing receptors but also $\alpha_{1/2/3}$ - and especially α_5 -containing GABA_A/BZ receptors. For the latter it had been observed that imidazo-benzodiazepines are generally α_5 receptor selective [104, 264]. A lipophilic pocket present in the general pharmacophore of all GABA_A/BZ receptors [265] seems to be smaller in α_1 -containing receptors than that present in α_5 -containing receptors [264]. This may account for the high affinity of zolpidem to α_1 receptors as it may lead to a strong lipophilic-lipophilic interaction only possible in the restricted space. Thus, increasing the size of the substituent at position R7 in Figure 3.3 increased the selectivity for α_5 -containing receptors and finally resulted in the development of RY-80, a high-affinity, high-selectivity ligand for α_5 receptors [266]. A similar strategy yielded the α_5 -selective ligand L-655,708 that exhibits an affinity in the same order of magnitude [267]. By exchanging two amino acids in α_1 into the corresponding residues of α_5 (α_1 S205T,V212I) the binding selectivity of α_5 against L-655,708 was transferred to α_1 -containing receptors [135]. Both ligands as well as a number of other ligands identified as α_5 selective [268] are negative modulators at the BZ recognition site. A good candidate for a positive modulator on this receptor subtype is still missing, if at all desirable in view of the fact that negative modulators at this site are developed as putative "cognition enhancers," thus leading to the speculation that positive modulators should lead to learning deficits.

In recent years a number of compounds have been published that are selective for the other members beside α_5 of the former BZ type II receptor group, that is, α_2 and/ or α_3 receptors [250, 269]. However, in most instances the compounds are not selective for the latter receptors in the sense that they bind with a high enough difference in affinity to produce a subtype-selective effect but they more pronouncedly differ in their efficacies exerted on α_1 , α_2 , α_3 , and α_5 receptors. One of these compounds is a negative modulator and anxiogenic in vivo at doses that minimize the occupancy at other than α_3 receptor subtypes, again suggesting that the α_3 receptor subtype may play a role in anxiety.

3.5 FUTURE DEVELOPMENTS

The existing mechanisms to extrinsically regulate the BZ-modulated GABAergic system are widespread and of tremendous clinical importance, although they represent only a substructure of the GABA_A system, which again is only a part of all inhibitory processes in the CNS. Nonetheless, the entire clinical or scientific potential of the BZ-dependent inhibition has probably not been exhaustively explored, mainly due to the large heterogeneity of the GABA_A/BZ receptor system. We are still awaiting $\alpha_i\beta_x\gamma_2$ ($i = 2, \dots, 6$) receptor subtype-specific drugs to come into clinical practice. Even less is known of BZ receptors containing the γ_3 instead of the γ_2 variant. There is no reason to believe that a minor receptor population is of minor importance [270, 271]. As well, the old story of partial versus full modulators, at both

sides of the scale, that is, positive and negative modulators, has not completely unfolded [272]. It is most likely that the use of these “fine-tuning” substances could finally benefit patients. In the extreme, this could lead to a drug only suitable for the treatment of a minor population of affected persons, regardless of whether diagnosed with anxiety-related diseases, epilepsy, insomnia, or drug-related problems. Another open question is the differential activation of synaptic versus extrasynaptic receptors, though it is open to discussion whether this can be achieved at all with any BZ ligand.

As reviewed elsewhere, genetic variations of the GABA_A receptor subunit may affect the susceptibility to many neuropsychiatric diseases [88]. When we better understand the underlying, perhaps neuronal cell population-specific, pathophysiological mechanisms, we may be able to find a stronger rationale for developing improved BZ ligand-based therapeutics.

4.1 INTRODUCTION

Rapid membrane effects of certain specific metabolites of steroid hormones provide a mechanism by which these metabolites can influence brain function and behavior in addition to the classical genomic actions of the parent steroid hormones. It was over 60 years ago that the pioneering studies of Hans Selye [1] reported the sedative–anesthetic activity of the hormones progesterone and deoxycorticosterone, where among 75 steroids tested by systemic (i.p.) administration in rodents, 5 β -pregnane-3,20-dione was the most active. This led to the introduction of hydroxydione sodium (21-hydroxy-5 β -pregnane-3,20-dione succinate, sodium salt) as the first steroidal anesthetic in 1955 [2]. However, it was Margarethe Holzbauer and her colleagues, during the 1969–1985 period, who isolated and identified pregnenolone, progesterone, allopregnanolone (3 α ,5 α -THP), epiallopregnanolone (3 β ,5 α -THP), allopregnanedione (5 α -dihydroprogesterone, or 5 α -DHP), 20 α -dihydroprogesterone, and allopregnanediol (5 α -pregnane-3 α ,20 α -diol) from ovarian venous blood of the rat and measured the ovarian content and secretion rates of these steroids during proestrus [3]. Their work was seminal but is often forgotten. Holzbauer and colleagues [4] further demonstrated the *in vivo* secretion of pregnenolone, progesterone, and 3 α ,5 α -THP by the adrenal gland of the rat in quantities similar to those secreted by the ovary during estrus. Their laboratory later provided an outdated organic extract of adrenal venous blood that was found to contain similar amounts of allotetrahydrodeoxycorticosterone (3 α ,21-dihydroxy-5 α -pregnan-20-one; alloTHDOC) and 3 α ,5 α -THP by radioimmunoassay (RIA) after separation of the steroid fraction by high-performance liquid chromatography (HPLC; R. Purdy, unpublished).

Two decades ago, γ -aminobutyric acid A (GABA_A) receptors were found to be sensitive to modulation by steroids, providing the first hint at a mechanism underlying the reported rapid (on the order of seconds) onset of action of these steroids. Subsequent to the initial demonstration by Harrison and Simmonds [5] that alphaxalone (3 α -hydroxy-5 α -pregnan-11,20-dione, a metabolite of 11-dehydrocorticosterone found in patients with congenital adrenal hyperplasia exhibiting 21-hydroxylase deficiency [6]) potentiated GABA-gated chloride currents, evidence has accumulated that alphaxalone and structurally related steroid derivatives have rapid membrane actions via an interaction with ligand-gated ion channels [7–11]. This evidence has given rise to the term *neuroactive steroids*, to distinguish them from *neurosteroids*, which are synthesized *de novo* from cholesterol in nervous tissue [12]. Behaviorally, GABA agonist neuroactive steroids are now recognized to possess especially potent anesthetic, hypnotic, anxiolytic, and anticonvulsant properties [13].

An understanding of the physiological role of neuroactive steroids is essential for their acceptance as modulators of stress and anxiety. It is apparent that these endogenously occurring steroids can reach levels in the rat brain that are capable of modulating GABA_A receptors. 3 α ,5 α -THP and alloTHDOC have been measured in brain and plasma, where their levels have been shown to fluctuate in response to stress in rats [14], and during the estrous and menstrual cycles of rats and humans, respectively [8]. Brain and plasma levels of 3 α ,5 α -THP temporally follow those of progesterone in the female rat (i.e., peak brain levels are observed during estrus in the rat and dramatically increase during pregnancy). Both 3 α ,5 α -THP and alloTHDOC are detectable in the normal male rat brain, but the levels are low under most circumstances. However, exposure of male rats to stressors such as ambient

temperature swim, footshock, or CO₂ inhalation resulted in a rapid 4- to 20-fold increase in brain levels of 3 α ,5 α -THP and alloTHDOC [14, 15] to the equivalent of 10–30 nM. Similar concentrations are observed in female rats during estrus, while concentrations can increase to approximately 100 nM during pregnancy [8, 16, 17], documenting that basal 3 α ,5 α -THP levels are higher in females than in males. These concentrations achieved *in vivo* are within the range of concentrations previously shown to potentiate the *in vitro* action of GABA at GABA_A receptors, suggesting that fluctuations in endogenous 3 α ,5 α -THP levels in rodents and both 3 α ,5 α -THP and 3 α ,5 β -THP levels in humans may be physiologically relevant. Evidence in support of this idea has been reviewed recently [18].

4.2 NEUROACTIVE STEROID CHEMISTRY AND PHARMACOLOGY

4.2.1 Brain and Peripheral Sources of Neuroactive Steroids

The term *neurosteroid* was introduced by Baulieu [19] to designate a steroid hormone derivative found in brain at concentrations that were independent of its plasma concentration, and the story of their discovery and function has been recently reviewed [12]. Endogenous concentrations of the progesterone metabolite 3 α ,5 α -THP have been detected in brain, plasma, and adrenals of male and female rats and in female rat ovaries [4, 8, 15, 20–23]. Brain 3 α ,5 α -THP levels have been detected in rat, mouse, dog, monkey, and human [8, 15, 22–28]. Compared with 3 α ,5 α -THP, the 5 β -reduced epimer is present in the rat in much lower abundance, if at all [27]. In addition, brain 3 α ,5 α -THP concentration is detectable at lower levels in adrenalectomized animals and is higher than plasma 3 α ,5 α -THP levels in intact animals [15, 22, 23].

A number of studies have established that the enzymes identified in classic steroidogenic tissues are likewise found in the nervous system [29]. Thus, the endogenous concentration of neuroactive steroids in the brain most likely reflects a combination of neuroactive compounds produced there *de novo* as well as steroids metabolized to neuroactive compounds in the brain but derived from circulating precursors. For this reason, it has recently been proposed that the definition of the term neurosteroid be broadened to include both sources of neuroactive steroids [29]. It also is noteworthy that all neurosteroids identified to date have been found to have neuroactive effects in some behavioral assay. The most recent study identified the major neurosteroid in the amphibian brain as 7 α -hydroxypregnenolone and subsequently determined that this neurosteroid acts as a neuronal activator to stimulate locomotor activity of breeding newts [30]. A schematic of the biosynthetic pathway of neuroactive steroid formation from cholesterol is depicted in Fig. 4.1.

Many methods have been used to quantify steroidal compounds. These include RIA, gas chromatography–mass spectrometry (GC/MS), HPLC, and liquid chromatography–mass spectrometry (LC/MS). While these techniques are successful in the analysis of steroids, it has been difficult to achieve quantitative analysis of small samples of neurosteroids because of their low concentrations in nervous tissues. Highly specific analytical methods are required to analyze small quantities of neurosteroids and their sulfates. Only with extremely sensitive methods of analysis is it possible to discover whether neurosteroids are synthesized in nervous tissues in quantities sufficient to affect neuronal activity and whether these neurosteroids are distributed uniformly in brain.

In the initial identification of dehydroepiandrosterone sulfate (DHEAS) [31] and pregnenolone sulfate (PREGS) [32] in the rat brain, a conjugated steroid fraction from brain extracts was prepared by chromatography on a column of Sephadex LH-20 and termed the *sulfate fraction*. This was free from unconjugated steroids, steroidal esters of fatty acids (lipoidal steroids), and steroidal glucosiduronates. This sulfate fraction was then hydrolyzed by solvolysis in ethyl acetate for 12–16 h at 37°C, and the hydrolyzed products were purified on a column of Lipidex 5000. The purified steroids were converted to their trimethylsilyl ethers and characterized by GC/MS as DHEA and PREG. On the basis that the levels of DHEA and PREG separately measured from the hydrolyzed sulfate fraction from brain extracts by RIA were markedly elevated compared to corresponding levels in blood and were found in extracts of brain tissue from rats previously adrenalectomized and orchietomized, DHEAS and PREGS were described as neurosteroids. A considerable body of electrophysiological, pharmacological, and physiological work has subsequently been carried out on these two presumed neurosteroid sulfates [33]. Meanwhile, Prasad et al. [34], demonstrated that when extracts of brain were heated and treated with triethylamine or various reducing agents such as ferrous sulfate, larger amounts of DHEA and PREG could be measured by GC/MS, compared to simple extraction without such treatments. They suggested that there might be steroidal hydroperoxides or peroxides in brain that had not yet been characterized.

Recently, two laboratories have independently cast grave doubts on the existence of significant amounts of DHEAS and PREGS in the adult rat brain. Using a non-exchangeable internal standard of [$3\alpha,11,11\text{-}^2\text{H}_3$] allopregnanolone sulfate and a tracer amount of [$1,2,6,7\text{-}^3\text{H}_4$] DHEA sulfate, Liu et al. [35] were unable to find detectable amounts of DHEAS, PREGS, and any of the four pregnenolone sulfates in nonhydrolyzed extracts of the adult Sprague–Dawley male and female rats using LC/micro-electrospray MS (LC/micro-ESI–MS). Shimada et al. [36] also have found only low amounts, 0.53 ± 0.28 ng/g, of PREGS in nonhydrolyzed extracts from adult Wistar rat brain using a unique derivatization procedure followed by LC/micro-ESI–MS. This compares to the value of about 20 ng/g brain of PREGS originally reported using solvolysis and measurement by RIA [32]. At present, there are no reports of other PREG-containing compounds that could account for this 20-ng/g brain level. Thus, the nature of the majority of PREG-containing compound(s) in the sulfate fraction from extracts of the rodent brain remains a mystery. It would require low microgram amounts of such a compound to be identified (after purification) using the most sensitive microprocedure of high-resolution proton magnetic resonance instrumentation.

4.2.2 Actions on GABA_A Receptors and Other Ligand-Gated Ion Channels

After alphaxalone was found to potentiate GABA-gated chloride currents [5], the progesterone metabolite $3\alpha,5\alpha$ -THP and the deoxycorticosterone metabolite alloTHDOC were determined to be potent positive modulators of GABA_A receptors. The relationship between plasma levels of corticosterone and alloTHDOC, measured by RIA in various stages of immobilization stress in adult male Sprague–Dawley rats, is illustrated in Fig. 4.2. It also has been demonstrated that alloTHDOC can be formed in brain and in the periphery from $3\alpha,5\alpha$ -THP through 21-hydroxylase activity [37] of cytochrome P450 (CYP2D) isoforms (Fig. 4.1). Therefore, we do not know at

Figure 4.2 The relationship between plasma levels of alloTHDOC and corticosterone in adult male Sprague–Dawley rats before and at various times during 30 min of immobilization stress. The rectangles are the values measured by RIA. The crosses are the values for the calculated regression line for $r = 0.94$. (Data from R. H. Purdy and N. Hagino, unpublished.)

present if the levels of alloTHDOC in brain are the result of synthesis from deoxycorticosterone (DOC) or allopregnanolone or both.

The above 3α -hydroxysteroids enhanced GABA-stimulated chloride flux in rat brain synaptoneurosomes at nanomolar concentrations [38] and interacted with known modulatory sites on GABA_A receptors in a noncompetitive manner [39, 40]. These pregnane neurosteroids have a saturated steroid A ring (see Fig. 4.3 for the steroid four-ring structures of the four epimeric pregnanolones formed in primates).

Notably, the interaction of pregnane neurosteroids with GABA_A receptors was stereospecific, in that the two key features necessary for activity were a 5α - or 5β -reduced steroid A ring and a 3α -OH group. The 3β analogues (i.e., 3β -hydroxy, 5α - or 5β -reduced pregnanes; epiallopregnanolone and epipregnanolone, respectively; Fig. 4.3) were devoid of activity or exhibited a partial inverse agonist profile. Progesterone, estradiol, corticosterone, 5α -dihydrotestosterone, and cholesterol were inactive *in vitro*. In the case of alloTHDOC, the 5β isomer (i.e., 5β -THDOC) had a partial agonist pharmacological profile [41]. Metabolism of $3\alpha,5\alpha$ -THP to allopregnanediol also yielded a steroid with efficacy as a partial agonist [42]. Among all the endogenously occurring steroids examined, $3\alpha,5\alpha$ -THP was the most potent, followed by its 5β stereoisomer (pregnanolone or $3\alpha,5\beta$ -THP) and alloTHDOC [40]. Importantly, the positive modulatory effect of neurosteroids at GABA_A receptors was relatively specific, in that these steroids did not interact with any other known neurotransmitter receptor in the nanomolar-to-low-micromolar concentration range.

Electrophysiological studies revealed that GABAergic steroids facilitated the open state of the GABA-gated channel (frequency and duration, nanomolar concentrations) and could directly activate GABA_A receptors in the absence of GABA at higher (micromolar) concentrations [43]. For a more detailed description of the

Figure 4.3 Structures of four epimeric pregnanolones. In the two allo (5α) steroids, the 3-hydroxyl group is axial in allopregnanolone (3α) and equatorial in epiallopregnanolone (3β), whereas in the 5β steroids the reverse is the case, with the 3-hydroxyl group being equatorial in pregnanolone (3α) and axial (3β) in epipregnanolone.

perturbation of GABA-gated ion channel kinetics by neurosteroids, the reader is referred to several excellent reports [44–46]. In general, the stereospecificity and enantioselectivity required for neuroactive steroid modulation of GABA_A receptors are features that would be consistent with a specific steroid binding site on GABA_A receptors [46–49]. However, use of recombinant subunit expression studies in conjunction with site-directed mutagenesis has not defined a steroid binding pocket on GABA_A receptors. Thus, the molecular mechanism(s) underlying the perturbation of GABA_A receptor function by neuroactive steroids remains to be determined.

Steroids with GABA-negative actions also have been reported (e.g., PREGS and DHEAS). Whereas PREGS and DHEAS antagonized GABA-gated chloride uptake and conductance in a noncompetitive manner [50, 51], PREGS also markedly reduced glycine-activated chloride currents [52] and enhanced *N*-methyl-D-aspartate (NMDA)-gated currents and elevations in intracellular calcium (Ca^{2+}) [53, 54]. Recent work also demonstrated that the $\text{C}_{3,5}$ reduction of cortisol, which is a primary regulator of the stress response in humans, generated compounds with negative modulatory activity at GABA_A receptors [55]. Notably, $3\alpha,5\beta$ -cortisol inhibited muscimol-stimulated chloride uptake with an median inhibitory concentration (IC_{50}) of $13\ \mu\text{M}$, whereas a $10\ \mu\text{M}$ concentration of cortisol, 11-deoxycortisol, 5α -dihydrocortisol, $3\alpha,5\alpha$ -cortisol, and $3\alpha,5\beta$ -11-deoxycortisol exhibited weak negative modulatory activity on muscimol-stimulated chloride uptake. Therefore, cortisol metabolism may produce steroids with GABA-negative action.

A possible role for pregnane 3-sulfate steroids in the modulation of NMDA receptor function also has been described. Although pregnanolone ($3\alpha,5\beta$ -THP; $50\ \mu\text{M}$) failed to alter NMDA induced cation influx through the NMDA receptor, its 3-position sulfate derivative dose dependently inhibited this NMDA receptor current in chick spinal cord neurons with an EC_{50} of $62\ \mu\text{M}$ [56], and it suppressed NMDA-mediated increases in intracellular Ca^{2+} in rat hippocampal neurons with an IC_{50} of

37 μM [57]. Similarly, 100 μM concentrations of either 3 α ,5 α -THP-sulfate or epipregnanolone-sulfate antagonized NMDA receptor cation conductance by 25 and 50%, respectively [58]. Pregnan-3-sulfates were found to modulate NMDA receptor function in a non-competitive fashion [56, 57], and their inhibitory interaction with this receptor likely involved a specific and separate binding site from positive modulators such as PREGS and related steroids [58–60]. Notably, sulfated and nonsulfated pregnane neurosteroids also had opposing effects on GABA_A receptor function [61]. Thus, even though sulfation of steroids is a major enzymatic reaction of metabolism, secretion, and homeostasis of steroids in the periphery, it may have a role greater than merely facilitating secretion because it also can change the pharmacological activity of steroids in the CNS [29]. While the role of sulfation in the modulation of excitatory and inhibitory ion channels by neurosteroids has yet to be demonstrated *in vivo*, it is possible that the addition and removal of the sulfate group could be a critical control point for neurosteroid modulation of neurotransmitter receptors [62].

In addition to the potent modulation of GABA_A receptor function by pregnane steroids, evidence also indicates that these steroids can interact with other ionotropic receptor systems at micromolar concentrations. Progesterone, 5 α -DHP, and 3 α ,5 α -THP inhibited $^{86}\text{Rb}^+$ efflux through neuronal nicotinic acetylcholine (nACh) receptors derived from mouse thalamus with apparent K_i values of 38, 5.3, and 17.5 μM , respectively [63]. In most cases, neurosteroid antagonism of nACh receptors *in vitro* was observed at concentrations between 10 and 100 μM —levels that are three- to five-fold greater than those estimated to be present in mammalian brain [64]. The inhibition of nACh receptors by progesterone occurred in a noncompetitive manner, did not require the presence of cognate ligand, and was likely dependent on the receptor subunit combinations expressed [65–67]. The attachment of the side chain with a β orientation at the 17 position of the neurosteroid imparted greater inhibitory potency at nACh receptors, whereas, in contrast to GABA_A receptors, the orientation of the hydroxyl group at the 3 position had little impact upon neurosteroid efficacy [68]. Although the sensitivity of various nACh receptor subunit combinations to neurosteroids has yet to be examined, it appears unlikely that a physiologically relevant concentration of pregnane steroids could alter nACh receptor activity.

Progesterone dose dependently inhibited serotonin-evoked currents through serotonin type 3 (5-HT₃) receptors from rat nodose ganglion with an EC₅₀ of 31 μM , whereas its A-ring-reduced metabolite 3 α ,5 α -THP (50 μM) exhibited no observable effect on this measure [69]. In contrast, *in vitro* studies suggest that pregnane steroids are functional antagonists at 5-HT₃ receptors. 3 α ,5 α -THP (10 μM) attenuated serotonin-mediated current by 30–35% in HEK 293 cells [70], while alloTHDOC and alphaxalone inhibited 5-HT-induced [^{14}C]-guanidinium influx in N1E-115 cells with IC₅₀ values of 19 and 44 μM , respectively [71]. Similar to neurosteroid interactions at nACh receptors, the substituent at the 3 position of the steroid A ring had little consequence for the antagonist profile of pregnane neurosteroids at 5-HT₃ receptors [70]. The degree of stereospecificity in neurosteroid modulation of 5-HT₃ receptors remains ambiguous, especially when considering a recent finding that the potency of neurosteroids in inhibiting 5-HT₃ receptor-mediated current was correlated with their lipophilicity [71], thereby suggesting a mechanism involving disruption of lipids adjacent to the receptor.

T-type (low-voltage-activated) Ca^{2+} channels, which act over a range of membrane potentials near the resting potential of most cells and are thought to play an important role in controlling cellular excitability [72–75], can be blocked by micromolar concentrations of $3\alpha,5\alpha$ -THP and alphaxalone [76]. The authors also demonstrated that the 5α -reduced neuroactive steroids were potent peripheral analgesic agents [76]. Notably, structural modifications that eliminated the blocking effect on T-type Ca^{2+} channels but maintained GABA_A receptor potentiation resulted in a complete loss of peripheral analgesic effects. Taken in conjunction with data indicating that GABA_A receptors play a role in centrally mediated effects of neuroactive steroids [77], it is likely that the peripheral analgesic action of 5α -reduced neuroactive steroids is mediated primarily by T channels and only to a smaller extent by GABA_A receptors.

Recent reports documenting neurosteroid interactions with metabotropic sigma 1 (σ_1) receptors are noteworthy. Importantly, the pregnane neurosteroids $3\alpha,5\alpha$ -THP and epipregnanolone were devoid of σ_1 receptor activity [78]. In contrast, progesterone has been identified as one of the most potent neurosteroid inhibitors of agonist binding to the σ_1 receptor [78, 79]. Furthermore, blockade of progesterone's conversion to its pregnane metabolites via a 5α -reductase inhibitor (finasteride) resulted in attenuated agonist binding to the σ_1 receptor, presumably due to augmented levels of progesterone [80]. Clearly, pregnane neurosteroids play little if any physiological role in modulating σ_1 receptor function.

Therefore, $3\alpha,5\alpha$ -THP, alloTHDOC, and $3\alpha,5\beta$ -THP, the three most potent pregnane neurosteroids characterized to date, have nanomolar potencies at GABA_A receptors, and consequently, these actions undoubtedly have physiological significance [18]. Interactions of pregnane neurosteroids at nACh, 5-HT₃, and NMDA receptors occur within the range 10–100 μM and are unlikely to have physiological relevance, even under challenge conditions (i.e., stress or pregnancy).

4.2.3 Enantiomeric Selectivity of Neuroactive Steroids

Studies of the binding and electrophysiological activity of neuroactive steroids have demonstrated that the effect of GABAergic steroids does not result from steroid binding at the benzodiazepine, barbiturate, picrotoxin, or GABA sites of these receptor complexes. These results have led to the concept of unique binding sites for a group of neuroactive steroids on GABA_A receptor complexes [10, 61, 81, 82]. Although there is no current demonstration of the effective binding of a radioactive steroid ligand to such sites, a significant correlation has been obtained between physiological and behavioral effects and *in vitro* structure-activity relationships of GABAergic steroids [83].

Specificity in the interaction of neuroactive steroids with neurotransmitter systems is most convincingly demonstrated by the results of Covey et al. [47] with non-naturally occurring enantiomers of both positive and negative modulators of GABAergic neurotransmission. Allopregnanolone ($3\alpha,5\alpha$ -THP) and pregnanolone ($3\alpha,5\beta$ -THP) occur naturally in one enantiomerically pure form, as illustrated in Fig 4.3. The mirror images of these compounds, known as ent steroids, are shown in Fig 4.4. and were prepared by total synthesis. Here the optically active centers at carbon atoms 3, 5, 8, 9, 10, 13, 14, and 17 are opposite to the configurations in the natural steroids (originally isolated from human pregnancy urine). High entioselectivity was

Figure 4.4 Enantiomeric structures of *ent*-allopregnanolone and *ent*-pregnanolone. These synthetic compounds are both much less potent positive modulators of GABA_A receptors when compared to their natural enantiomers shown in Fig. 4.3. [47].

found for $3\alpha,5\alpha$ -THP when compared to *ent*- $3\alpha,5\alpha$ -THP. However, the entioselectivity for $3\alpha,5\beta$ -THP was markedly lower than that for $3\alpha,5\alpha$ -THP, consistent with different binding sites for 3α -hydroxy- 5α - and 3α -hydroxy- 5β -pregnanes. This difference was confirmed by the use of the first specific inhibitor of $3\alpha,5\alpha$ -THP, 3α -hydroxy- 5α -androst-16-ene-17-phenyl, which only weakly affects the *in vitro* and *in vivo* activity of $3\alpha,5\beta$ -THP [84].

4.2.4 Behavioral Effects

Neurosteroids that are positive modulators of GABA_A receptors possess anesthetic [85], hypnotic [86], anticonvulsant [17, 87–93], and anxiolytic [93–100] properties [13]. While $3\alpha,5\beta$ -THP was equipotent with $3\alpha,5\alpha$ -THP as an anxiolytic [95, 98, 101], it was much less potent as an anticonvulsant [101]. The 3β -stereoisomer of $3\alpha,5\alpha$ -THP was inactive in all tests. The effects of pregnane neurosteroids on cognitive function also have been extensively evaluated on conditioned learning and spatial learning tasks [102]. Regardless of the paradigm utilized (e.g., win-shift foraging paradigm, Morris water maze, Y-maze discrimination task), $3\alpha,5\alpha$ -THP, $3\alpha,5\beta$ -THP, and epipregnanolone exhibited a behavioral profile associated with working (spatial) memory deficits [102–105]. Collectively, these behavioral responses closely follow the anticipated patterns based on *in vitro* evidence and suggest that GABAergic steroids modify the functioning of central GABA_A receptors *in vivo*. Therefore, if the findings with exogenous administration of $3\alpha,5\alpha$ -THP are indicative of GABA_A receptor sensitivity to endogenous $3\alpha,5\alpha$ -THP concentration, then endogenous neurosteroids may participate in the physiological control of central nervous system (CNS) excitability.

4.3 EFFECTS OF NEUROSTEROIDS IN ANIMAL MODELS OF ANXIETY AND STRESS

Rodent models of human generalized anxiety symptoms take advantage of a variety of behaviors within the natural behavioral repertoire of rodents that have been interpreted to be “anxiety-like.” While these tasks are based on putative parallels between human and rodent symptoms of anxiety, it is not known whether a rodent experiences “anxiety” in the same way as humans. With this in mind, different behavioral principles seem to underlie various animal models of anxiety such that paradigms can be based on spontaneous exploration, a learned response, conflict

behavior, or a combination of these ideas. Most of these tasks utilize approach–avoidance behaviors in rodents that can provide a good indication of a rodent’s response to conflict in the natural environment. A number of detailed reviews are available on this topic [106–111]. Here, we will briefly describe tasks that have been well validated in terms of their specificity for anxiety-like behaviors and the ability to demonstrate anxiolytic effects with a variety of GABAergic neuroactive steroids. The paradigms described below are good choices for testing hypotheses related to the modulatory effect of neuroactive steroids on anxiety-related behavior. However, these tests also can be influenced by factors unrelated to anxiety. It is therefore recommended that any animal model be tested on more than one anxiety test, so that different sensory and motor modalities can be examined. Alternatively, anti-anxiety effects in multiple tasks that measure both increases and decreases in responding can control for motor effects.

4.3.1 Elevated-Plus Maze

One of the most well-validated animal models of anxiety is the elevated-plus maze task [112–115], as it is able to detect both anxiolytic and anxiogenic agents in rodents [113]. This task is based on a rodent’s natural avoidance of open, elevated alleys that was described almost 50 years ago [116]. Thus, the test sets up a conflict for the rodent between its tendency to explore a novel environment and its tendency to avoid the aversive properties of an open, elevated environment. Typically, mice and rats perform similarly on the elevated-plus maze, although performance on this task can be influenced by light level [117].

The apparatus consists of two open and two enclosed horizontal perpendicular arms of the same size and shape that are at right angles to each other. These four arms extend from a central platform (approximately 5×5 cm), forming the shape of a plus, and are elevated approximately 50 cm above the floor. The two open arms are simple runways with a minimal lip that allows the animal to see the edge without falling off the arm. The enclosed arms are closed runways with high walls that can be opaque. Typically, an animal is placed on the central platform (i.e., at the junction of the four arms) and allowed to explore freely for 5 min. During the 5-min test period, the number of entries into the open and closed arms as well as the amount of time spent in the open and closed arms is measured. Ideally, for an arm entry to be measured, all four paws should be within the arm. If the task is videotaped, additional anxiety-related behaviors can be quantified (see below) [107, 118]. However, the most commonly reported index of anxiety with this task is the percentage of open-arm entries or open-arm time, which is a proportion of the total number of entries or total time of the test, multiplied by 100. Normally, mice prefer the closed arms of the elevated-plus maze. Anxiolytic drugs typically increase the proportion of open-arm entries and the time spent on the open arm [93, 112, 118–122], whereas anxiogenic drugs or treatments decrease the percentage of open-arm entries or time [113, 123].

Comprehensive profiling of behavior also can be achieved by performing detailed videotaped analysis of untreated rodents on the elevated-plus maze, yielding a catalog of readily identifiable behaviors that have been referred to as *risk assessment* [107]. Examples include rearing, head dipping, stretched attend postures, closed-arm returns (i.e., doubling back in, rather than leaving, a closed arm), and several non

exploratory behaviors [118]. “Protected” versus “unprotected” forms of these behaviors can be differentiated based on wall contact. This distinction is based on recent evidence that the most important feature producing open-arm avoidance is the absence of thigmotactic cues (i.e., walls), rather than the height of the maze [123]. Thus, this ethological approach provides multidimensionality to the analysis of elevated-plus maze behavior [107].

An important consideration for interpretation of elevated-plus maze data is that any treatment that affects motor behavior may influence the percentage of open-arm entries or time spent in the open arms. This is due to the fact that the paradigm requires the animal to locomote for a period of 5 min. However, the total number of entries as well as number of entries into the closed arms will give an indication of whether the treatment is influencing activity per se, and closed-arm entries are the most validated measure of activity [106, 124]. In this case, independent paradigms that specifically analyze locomotor behavior are recommended.

Consistent with a GABA-agonist pharmacological profile, the neurosteroids $3\alpha,5\alpha$ -THP and $3\alpha,5\beta$ -THP exhibit significant anxiolytic effects on the elevated plus-maze following systemic (1–20 mg/kg, i.p.) [93, 98, 100, 125] or intracerebroventricular (1.25–10 μ g, i.c.v.) [95] administration. Both steroids significantly increased the proportion of open-arm entries and open-arm time. A similar anxiolytic effect was observed following administration of alloTHDOC (5–20 mg/kg, i.p.) [100]. Detailed behavioral analyses demonstrated that the anxiolytic effects of alloTHDOC, $3\alpha,5\alpha$ -THP, and $3\alpha,5\beta$ -THP did not reliably decrease measures of risk assessment and were not associated with a change in activity level, in contrast to the anxiolytic profile of a 1-mg/kg dose of diazepam [100]. However, in one study, a decrease in total entries, taken as an index of sedation, was observed following administration of a 10 μ g (i.c.v.) dose of $3\alpha,5\alpha$ -THP [95]. Systemic administration of allopregnanediol, a partial agonist at GABA_A receptors, produced anxiolytic effects within a dose range of 10–40 mg/kg, i.p. [126]. Both systemic and i.c.v. administration of the 3β -stereoisomer of $3\alpha,5\alpha$ -THP ($3\beta,5\alpha$ -THP) had no effect on elevated-plus maze behavior or locomotor activity [95, 100], consistent with reports of its inability to potentiate GABA-gated currents. Therefore, GABA agonist neurosteroids produce anxiolytic effects in the rodent elevated-plus maze, and their anxiolytic profile can be partially distinguished from that of a well-characterized benzodiazepine (i.e., diazepam).

Recent findings in progesterone receptor (PR) knockout mice indicate that the anxiolytic effect of progesterone was due to its conversion to $3\alpha,5\alpha$ -THP [127]. With this mouse model, a targeted null mutation of the PR gene eliminated the function of both PR-A and PR-B subtypes of the PR. Administration of progesterone (50 and 75 mg/kg) or $3\alpha,5\alpha$ -THP (2 and 5 mg/kg) to PR knockout and wild-type mice significantly increased open-arm entries and time. Notably, the anxiolytic effect of progesterone was blocked by pretreatment with finasteride (50 mg/kg), a 5α -reductase inhibitor that prevents the conversion of progesterone to $3\alpha,5\alpha$ -THP, in both genotypes [127]. Finasteride pretreatment did not alter $3\alpha,5\alpha$ -THP's anxiolytic effect in either genotype. These results indicate that the anxiolytic action of progesterone does not require PRs, but does require its conversion to $3\alpha,5\alpha$ -THP.

In contrast, neurosteroids that are noncompetitive antagonists of GABA_A receptors have mixed effects on anxiety-related behavior. For example, systemic administration of DHEA and DHEAS exhibited anxiolytic effects on the elevated-plus maze [128], whereas pregnenolone had anxiogenic properties [129]. PREGS had

a biphasic effect on elevated-plus maze behavior, exhibiting anxiolytic effects at low doses and anxiogenic effects at increasing doses [129]. Although data for DHEAS and PREGS are limited, it is possible that the mixed effects of these GABA antagonist steroids reflect confounding effects on activity level or the reduced ability of sulfated steroids to cross the blood–brain barrier.

Recent findings indicate that microinjection of GABA agonist neuroactive steroids or agents that increase neurosteroid levels into the hippocampus can produce anxiolytic effects. Specifically, microinjection of 2.5 and 5- μ g doses of pregnanolone (3 α ,5 β -THP) into the dorsal hippocampus of male rats significantly increased the proportion of time spent in the open arms of the elevated-plus maze [130]. Similar behavioral effects were seen when the hippocampus was microinjected with agonists of peripheral mitochondrial benzodiazepine receptors, which led to an increase of brain 3 α ,5 α -THP [131].

With regard to the neurobiology of stress and anxiety, the role of the hippocampus has been described as a “comparator system” that can detect whether a threat is familiar or novel, thus requiring either a conditioned automatic response or higher order processing, respectively [132]. The septum, posterior cingulate, and thalamic nuclei also have been implicated in this role [133]. Overall, the hippocampus is important in traumatic memory consolidation and, with the entorhinal cortex, in contextual fear–conditioned behaviors. Projections from the hippocampus to the bed nucleus of the stria terminalis (BNST) and from the BNST to hypothalamic and brain stem sites may be involved in the expression of contextual fear conditioning (see Section 4.3.4).

4.3.2 Geller–Seifter and Vogel Conflict Tests

Both of these paradigms are conflict tests that utilize operant responding for a food reward [134] or a water reward [135], with electric shock as the aversive component in both tasks. The number of lever presses for either the food or water reward, in conjunction with a mild shock that is delivered on a fixed-ratio schedule, is the variable of interest. Anxiolytic drugs typically increase the number of lever presses, or the number of shocks that are acceptable, for the food or water reward. Although weeks of training on the lever-press task are required, these paradigms have the advantage that once stable performance baselines are established, the same animal can be used repeatedly to examine drug effects by comparing these data with its baseline (i.e., it is its own control). These tasks also have the advantage of an additional internal control, unpunished responding, that gives an indication of nonspecific drug effects. While both the Geller–Seifter and Vogel paradigms have been used primarily in rats, there are data on neurosteroid effects in mice as well.

Early work in Sprague–Dawley rats and Swiss Webster mice demonstrated that both alloTHDOC (10, 15, and 20 mg/kg, i.p.) and 3 α ,5 α -THP (20 mg/kg, i.p.) had anxiolytic effects in the Vogel and Geller–Seifter conflict tests, respectively [94, 97]. Both steroids significantly increased punished responding without significantly influencing unpunished responding. However, a trend for sedation was found following the highest dose of alloTHDOC. Subsequent studies have confirmed these initial findings and demonstrated that systemic administration of 3 α ,5 α -THP [98, 99], 3 α ,5 β -THP [98], and alphaxalone [96] significantly enhanced punished drinking, consistent with their positive modulatory effects at GABA_A receptors.

Another study compared the anxiolytic potential of four pregnanediols, differing only in the stereochemical orientation (α or β) of the steroid A ring and the 20-OH group [126]. The effects of these pregnanediols were examined in the Vogel test following i.c.v. administration and compared to those of their 20-ketone analogs (i.e., $3\alpha,5\alpha$ -THP and $3\alpha,5\beta$ -THP). All four pregnanediols significantly enhanced punished drinking at doses ranging from 10 to 60 μg , whereas $3\alpha,5\alpha$ -THP and $3\alpha,5\beta$ -THP enhanced punished responding when administered at 2.5- and 5- μg doses, respectively [126]. Doses of $3\beta,5\alpha$ -THP up to 100 μg were inactive in the Vogel test, consistent with this steroid's lack of activity at GABA_A receptors. These results suggest that some endogenously occurring pregnanediol metabolites (e.g., Fig. 4.3) also may influence physiological processes related to anxiety via an action at GABA_A receptors, in addition to the actions of their parent steroids $3\alpha,5\alpha$ -THP and $3\alpha,5\beta$ -THP.

As discussed in chapters on the neurobiology of stress and anxiety disorders, the amygdala plays a pivotal role in the assessment of and response to danger. The amygdala has extensive connections to the cortex and locus ceruleus and projections to the striatum, hypothalamus, midbrain, and brain stem. Thus, it can exert control over locomotor, neuroendocrine, autonomic, and respiratory responses. In addition, the amygdala also is seen as the common pathway and processor of "fear" [136]. Recent work demonstrated that infusion of $3\alpha,5\alpha$ -THP (8 μg per side) into the central nucleus of the amygdala (CeA) of male and ovariectomized (OVX) female rats produced a significant anxiolytic effect, measured by a significant increase in punished responding in the modified Geller Seifter conflict test [137]. Likewise, bilateral infusion of $3\alpha,5\alpha$ -THP (8 μg per side) into the CeA significantly increased open-arm time and open-arm entries on the elevated plus maze, compared to vehicle-infused controls. Bilateral infusion of the noncompetitive GABA_A receptor steroid antagonists PREGS (0.0018 μg side) or DHEAS (2–8 μg per side) into the CeA had no effect on punished or unpunished responding, nor did i.c.v. administration of these two steroids at doses ranging from 1 to 20 μg [137]. Collectively, these findings suggest that the CeA is a key region involved in the mechanisms underlying the anxiolytic effects of $3\alpha,5\alpha$ -THP.

4.3.3 Light–Dark Box

Conceptually similar to the elevated-plus maze, the light–dark exploration task is based on the conflict between a rodent's tendency to explore a novel environment and the aversive properties of a brightly lit open field [138, 139]. The apparatus is an acrylic box divided by a panel into a large open area (28 cm long \times 28 cm wide) and a slightly smaller enclosed area that is painted black (28 cm long \times 19 cm wide). The open area is illuminated to 355 lux, whereas the light level in the dark chamber is low (2 lux). Typically, the animal is placed in the center of the light area, facing away from the entrance to the dark chamber, and behavior is recorded for 5–10 min. The number of transitions between the light and dark chambers, the time spent in both chambers, as well as the latency to enter the dark chamber, can be quantified by photocell array or manually. A chamber crossing is defined as all four paws of the mouse inside the chamber. The number of transitions and the time spent in the light chamber are the most commonly used variables. Anxiolytic drugs increase the number of transitions as well as the amount of time spent in the light chamber, relative to the dark chamber, which are believed to be indicators of the animal's willingness to explore the brightly lit open area [94, 139].

Interpretation of the light–dark box data can be confounded by effects of treatments on locomotor activity, particularly when the number of transitions is the only variable that is utilized. This appears to be more of a problem with anxiogenic drugs or treatments, as low levels of general activity have been shown to produce false positives [140]. Thus, it is recommended that independent testing for locomotor function be conducted in new classes of drugs in order to detect stimulant or sedative properties that could confound interpretation of the light–dark transition measure.

Early work found that alloTHDOC (7.5–15 mg/kg, i.p.) significantly increased the number of light–dark transitions in Swiss Webster mice [94]. There was no decrease in generalized locomotion, although a trend for sedation was found following administration of a 30-mg/kg dose of alloTHDOC. Subsequent studies in Swiss Webster mice documented dose-dependent anxiolytic effects of alloTHDOC (20 and 40 mg/kg, i.p.) and $3\alpha,5\alpha$ -THP (10–40 mg/kg, i.p.) with the light–dark box and that the 3β stereoisomer of $3\alpha,5\alpha$ -THP was inactive in this task [97, 98].

4.3.4 Acoustic Startle and Fear-Potentiated Startle

It was over 50 years ago that conditioned fear could be revealed by the magnitude of the startle response to an auditory stimulus [141]. This fear-potentiated startle paradigm involves pairing a neutral stimulus (e.g., light) with a footshock prior to the auditory stimulus [136, 142]. During testing, startle is elicited by the auditory stimulus alone (normal acoustic startle) or the auditory stimulus in the presence of the footshock-paired neutral stimulus (potentiated startle). The fear-potentiated startle effect only occurs following prior light–shock pairings, and not when lights and shocks have been presented in an unpaired or random fashion [143]. Presenting the conditioned stimulus repeatedly without further light/shock pairings will extinguish the prior fear conditioning (i.e., enhanced startle response) [144]. Notably, anxiolytic drugs reduce fear potentiated startle, whereas drugs that induce anxiety in people will increase potentiated startle in rodents [136].

Intracerebroventricular administration of corticotropin-releasing factor (CRF) can increase the amplitude of the acoustic startle response [145–147], whereas CRF peptide antagonists exhibit anxiolytic effects in the fear-potentiated startle paradigm [137, 147, 148]. Recently, it was reported that CRF-potentiated startle was significantly reduced in OVX female rats treated acutely or chronically with progesterone as well as in lactating female rats (high progesterone levels) [149]. Administration of $3\alpha,5\alpha$ -THP (10 mg/kg, i.p.) had a similar effect, suggesting that the effect of progesterone to reduce CRF-potentiated startle might be due to its metabolism to $3\alpha,5\alpha$ -THP. However, neither chronic progesterone nor $3\alpha,5\alpha$ -THP attenuated fear-potentiated startle [149]. Taken in conjunction with work indicating that the BNST, but not the CeA, is required for the elevation of startle after CRF infusion [150], the disparity in the effects of progesterone and $3\alpha,5\alpha$ -THP on CRF- versus fear-potentiated startle may reflect differential sensitivity of these brain regions to the steroids.

4.3.5 Mirrored Chamber

The chamber-of-mirrors procedure was first described in 1990 [151] as a measure of anxiety in rodents. This test generates an approach–avoidance conflict behavior which is based on early work [152] indicating that several vertebrate species demonstrate

behavioral responses to mirrors such as aggressive threats and approach–avoidance behavior. The chamber consists of a mirrored cube 30 cm on a side which is open on one side and placed inside the center of an opaque Plexiglas box (40 × 40 × 30.5 cm). Thus, a 5-cm corridor completely surrounds the five-sided mirrored chamber. A sixth mirror is placed against the container wall opposite the single open side of the mirrored chamber. With the exception of the initial report in which mice were tested for 30 min [151], mice are placed in the corridor outside the mirrored chamber. Latency to enter the mirrored chamber, number of entries, time per entry, and total time in the mirrored chamber are recorded for a period of 5–10 min [153–156]. In this assay, a mouse avoids entering the mirrored chamber, whereas it will enter readily if the walls of the chamber are not mirrored [151]. However, a recent study in three inbred strains of mice in which the mirrors in the chamber were replaced with white or gray tiles suggested that a brightness or position effect in the chamber also could explain the avoidance behavior in certain genotypes [156]. Nonetheless, the mirrored-chamber procedure has been validated in terms of being responsive to a wide spectrum of anxiolytic agents at doses that do not affect locomotor activity [151, 153–155]. Recently, a modified version of the mirrored chamber was validated in the mouse to detect both anxiolytic and anxiogenic agents [157].

Neurosteroids also exhibited anxiolytic effects, measured by the behavior of mice in the mirrored test of anxiety [155]. Administration of progesterone (1–10 mg/kg) or its reduced metabolite 3 α ,5 α -THP (0.5 and 1 mg/kg) produced a dose-dependent anxiolytic response, measured by increased number of entries and total time spent in the mirrored chamber as well as by decreased latency to enter the chamber. Consistent with the GABA agonist profile of 3 α ,5 α -THP, the anxiolytic effect was blocked by coadministration of picrotoxin, a GABA_A receptor chloride channel antagonist. In contrast, administration of a neurosteroid with GABA antagonist properties (DHEAS, 1 and 2 mg/kg) produced an anxiogenic response, measured by a decrease in the number of entries and total time spent in the mirrored chamber as well as an increase in the latency to enter the chamber. Therefore, both anxiolytic and anxiogenic effects of neurosteroids have been demonstrated that are consistent with their activity at GABA_A receptors.

4.3.6 Open-Field Activity

Open-field activity is the oldest and simplest measure of rodent emotional behavior [158, 159]. Briefly, spontaneous exploratory locomotion, proximity to the walls and central arena, and number of fecal boli deposited are quantified in a brightly lit novel open field for a period of 5–10 min. Whereas fully automated systems are widely used, the scoring also can be performed manually. Thigmotaxis is measured by comparing activity in the center with activity in the perimeter of the open field. An animal exhibiting high perimeter and low center activity would be interpreted as possessing high levels of anxiety. However, an important distinction is that open-field activity is not a specific measure of anxiety or as specific a measure of anxiolytic drug response, compared to other tasks described in this section. Nonetheless, open-field activity does provide a useful measure of normal versus abnormal exploratory behavior. With this *proviso* in mind, early work documented that systemic administration of 3 α ,5 α -THP and alloTHDOC (20 mg/kg, i.p.)

significantly increased activity in the open-field test, whereas the 3 β epimer of 3 α , 5 α -THP was inactive [97].

4.3.7 Defensive Burying Behavior

Defensive burying refers to rodent behavior of displacing bedding material to remove or avoid aversive (unfamiliar and/or harmful) objects from their habitat. Together with flight, freezing, and fighting, defensive burying is part of the behavioral repertoire of unconditioned defensive reactions in an animal [160]. The shock-prod defensive burying procedure was first described in 1978 by Pinel and Treit [161]. Using a familiar test chamber, the animal is confronted with a wire-wrapped prod (or probe) that is inserted through a small hole in one of the test chamber walls so that the prod is approximately 2 cm above the bedding. Following the first contact with the electrified prod (in which the animal receives an electric shock), the animal's behavior is either observed or videotaped for a test session of 10–15 min. Typically, rodents will cover the shock source with cage litter or bedding. The latency and time to the first prod contact (shock) and the latency time to initiate burying behavior are recorded. The most commonly used measures of this defensive behavior have been the frequency and duration of time spent on prod-directed burying behavior as well as the height of the bedding material around the shock prod. In general, anxiolytic drugs suppress conditioned defensive burying, as measured by a reduction in the mean duration of burying behavior [160].

As with other animal models of anxiety-related behaviors, an ethological analysis of several concurrent and competitive behavioral indices of fear/anxiety, avoidance, reactivity, and exploration can provide a better understanding of the full defensive behavioral repertoire in rodents [160]. The following behavioral categories can be distinguished: ambulation, rearing, immobility, burying, grooming, prod-explore (i.e., oriented toward prod in a stretch/attend-like posture), and eating/drinking. One benefit of this ethological analysis stems from the fact that there is considerable variation across individual animals and studies in the mean time that animals engage in burying, which also represents only a small portion (between 3 and 30%) of the behaviors exhibited during the 10–15-min test. Thus, in addition to measuring defensive burying, one can quantify other avoidance/defensive behaviors (i.e., decreased prod exploration, increased freezing/immobility) as well as general exploratory and other behaviors (i.e., ambulation, rearing, grooming, and consummatory activities). While this paradigm has the advantage of requiring much less ambulatory locomotor activity than other tasks, it does have the potential confound that treatments producing behavioral sedation may produce false positives on this task (i.e., decreased defensive burying due to sedation). This task also has been well characterized for rats but not for mice.

The GABAergic neuroactive steroids 3 α ,5 α -THP (0.25–1.0 mg/kg) and 3 α ,5 β -THP suppressed burying behavior in this task, consistent with their anxiolytic profile [125, 162]. Progesterone (1–4 mg/kg) also was effective, whereas PREGS (1–4 mg/kg) was not [162]. Additional studies determined that microinjection of 3 α ,5 β -THP into the dorsal hippocampus or the lateral septum significantly decreased burying behavior [130]. These microinjection studies are consistent with data indicating that the posterior parts of the septal region, the dorsal hippocampus, the caudal shell of the nucleus

accumbens, and the dorsal raphe nuclei are critical parts of the neural circuitry underlying defensive burying [160].

4.3.8 Separation-Induced Ultrasonic Vocalizations

The rat pup ultrasonic vocalization procedure has been shown to detect a wide range of anxiolytic and anxiogenic compounds [163]. In rat pups, vocalizations in the frequency range of 35–45 kHz are produced in the first two postnatal weeks and are associated with social isolation. Most investigators count the number of calls using a microphone sensitive to high-frequency sounds connected to a signal detection device, such as a bat detector, that transduces the sounds into the audible range. However, it also is recommended that nonvocal variables such as changes in ambient and body temperature, locomotion, and coordination should be monitored to determine whether the effects of a treatment are specific for vocal behavior [163]. Variations of this procedure have been referred to as maternal separation, early deprivation, or social isolation [164].

Initial studies determined that benzodiazepine agonists (such as diazepam and chlordiazepoxide) decreased the number of ultrasonic vocalizations in isolated rat pups at doses lower than those that produced muscle relaxation and sedation [165]. The GABAergic neurosteroids $3\alpha,5\alpha$ -THP and alloTHDOC also significantly decreased the number of ultrasonic vocalizations in isolated rat pups [166–169]. Repeated administration of alloTHDOC to infant rats during postnatal days 2–10 prior to recurring separation from their mothers significantly attenuated the increase in anxiety-related behavior that was evident in rats administered vehicle, when the animals were tested on the elevated-plus maze as adults [168]. In the study by Patchev et al. [168], repeated maternal separation also produced neuroendocrine alterations related to dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis in adult rats, and these endocrine responses were significantly reduced in the animals administered repeated alloTHDOC as infants. In contrast, a study that utilized a slightly different maternal separation procedure did not observe a difference in anxiety related behavior in adult rats that had been repeatedly separated from their mothers as infants versus non-isolated controls [169]. However, as adults, non-isolated controls treated daily with $3\alpha,5\alpha$ -THP during postnatal days 2–6 exhibited less anxiety-like behavior than all other groups, including isolated rats treated with $3\alpha,5\alpha$ -THP. Postnatal treatment with $3\alpha,5\alpha$ -THP also eliminated the sex difference in anxiety-related behavior that was apparent in non-injected adult rats. In general, these studies suggest that chronic treatment with the GABAergic neurosteroids alloTHDOC and $3\alpha,5\alpha$ -THP may offset the behavioral and neuroendocrine changes that occur as a result of adverse early-life events.

4.3.9 Modified Forced-Swim Test

The forced-swim test is considered an animal model of depression, rather than of anxiety. Since many of the core symptoms of depression are difficult to measure in laboratory animals, many of the available animal models of depression are based on the actions of known antidepressants or on the responses to stress [170]. The forced-swim test was initially developed in the rat [171] and later in the mouse [172]. In this model, rodents are forced to swim in a confined environment. The animals initially

swim around and attempt to escape and eventually assume an immobile position. On subsequent tests, the latency to immobility is decreased [170, 173]. The immobility is thought to reflect either a failure of persistence in escape-directed behavior (i.e., behavioral despair) or the development of passive behavior that disengages the animal from active forms of coping with stressful stimuli. A drug or treatment that produces an increase in immobility would be considered to produce depressive-like behavior, whereas a drug that increases escape-directed behavior (i.e., decreased immobility) would be considered to have an antidepressant effect. However, one drawback of the Porsolt forced-swim test is that it is not sensitive to the selective serotonin reuptake inhibitor (SSRI) class of antidepressant compounds.

In an effort to enhance the sensitivity of the forced-swim test in rodents so that it could be SSRI responsive, several simple procedural modifications were made [173]. Increasing the water depth to 30 cm produced less immobility time because animals could not contact the cylinder bottom with their paws. Rating the predominant behavior over 5-s intervals allowed the distinction of the following behaviors: climbing, horizontal swimming, and immobility. With regard to the putative antidepressant effects of neurosteroids, systemic (0.5, 1 or 2 mg/kg, i.p.) or i.c.v. (1 or 2 μ g per mouse) administration of $3\alpha,5\alpha$ -THP dose dependently reduced the duration of immobility in the modified Porsolt forced-swim test [174, 175]. This antidepressant-like effect of $3\alpha,5\alpha$ -THP was potentiated by pretreatment with the GABA_A receptor agonist muscimol [174] or ethanol [175], whereas it was blocked by pretreatment with the GABA_A receptor antagonist bicuculline. Administration of progesterone (2 mg/kg) to OVX female rats also was effective at producing effects in the forced-swim test that were similar to that of the tricyclic antidepressants [176]. The ability of progesterone to decrease immobility by increasing climbing behavior was comparable to that observed during days 14 and 17 of pregnancy. Thus, physiological states in which progesterone levels are high can produce antidepressant-like effects, presumably due to progesterone's reduction to $3\alpha,5\alpha$ -THP.

Chronic ethanol withdrawal, which has been reported to decrease endogenous $3\alpha,5\alpha$ -THP levels (see Section 4.4.4), produced an increase in immobility on the modified forced-swim test [175]. Notably, subthreshold doses of $3\alpha,5\alpha$ -THP (0.25 or 0.5 μ g per mouse) reversed the depressive-like symptoms associated with ethanol withdrawal. Recent findings also indicated that withdrawal from daily progesterone injections significantly increased immobility in the modified forced-swim test in female DBA/2 mice (E. H. Beckley and D. A. Finn, unpublished results). There was a further increase in immobility when the metabolism of progesterone was blocked with administration of finasteride, suggesting that withdrawal from progesterone or progesterone metabolites produced an increase in depressive-like behavior. These findings are consistent with recent work suggesting that some symptoms of progesterone withdrawal are due to withdrawal from $3\alpha,5\alpha$ -THP [177, 178]. Although speculative at this point, these findings are consistent with an inverse relationship between fluctuations in endogenous $3\alpha,5\alpha$ -THP levels and depressive-like symptoms (i.e., \uparrow $3\alpha,5\alpha$ -THP, \downarrow depression; \downarrow $3\alpha,5\alpha$ -THP, \uparrow depression).

4.3.10 Mild Mental Stress Models and Social Isolation

As described in Section 4.1, acute exposure of male rodents to a variety of stressors rapidly increased brain $3\alpha,5\alpha$ -THP and alloTHDOC to the equivalent of 10–30 nM

concentrations [14, 15]. Recent work also demonstrated that immobilizing rats on their backs for 20 min produced a significant increase in brain $3\alpha,5\alpha$ -THP levels as well as in levels of the precursor steroids pregnenolone, progesterone, and 5α -DHP [179]. Notably, when the vocalizations of the rats were recorded during the period of immobilization and subsequently played for 1 h to a group of unrestrained rats (referred to as mild mental stress or “din stress” by the authors), there was a slight but significant increase in brain $3\alpha,5\alpha$ -THP, 5α -DHP, progesterone, and pregnenolone levels in 66% of the rats [179]. Thus, acute exposure to physical stressors or stressors encompassing a psychological component can increase the synthesis of GABAergic neuroactive steroids to levels that should facilitate GABAergic neurotransmission in the brain.

In contrast, long-term social isolation after weaning significantly decreased brain $3\alpha,5\alpha$ -THP and alloTHDOC levels in male rodents [180–182]. There is conflicting evidence on the specific point(s) in the neurosteroid biosynthetic pathway where social isolation might be altering GABAergic neurosteroid levels. Whereas one study demonstrated that social isolation also decreased brain pregnenolone and progesterone levels [181], a second study provided evidence that the effect of social isolation occurred at a point downstream from progesterone [182]. In the study by Dong et al. [182], social isolation did not alter progesterone levels, but it significantly decreased the expression and protein levels of the enzyme 5α -reductase (see Fig. 4.1 for biosynthetic pathway). Nonetheless, the decreases in GABAergic neurosteroid levels were associated with an increase in anxiety-like behavior, measured by a significant decrease in percentage of open-arm time on the elevated-plus maze and a significant decrease in punished responding in the Vogel conflict test [181]. Social isolation also produced a decrease in biochemical and electrophysiological measures of GABA_A receptor function [181] as well as decreased sensitivity to the hypnotic effect of GABAergic compounds [180, 183]. Thus, the period of exposure to stress may produce opposite effects on endogenous neuroactive steroid levels in the brain.

4.4 NEUROACTIVE STEROID INTERACTIONS WITH STRESS-INDUCED BEHAVIORS

From the results summarized in Section 4.3, it is apparent that GABA agonist neurosteroids have anxiolytic properties. However, their role as endogenous modulators of anxiety is less clear. For example, systemic administration of progesterone has anxiolytic effects, measured by elevated-plus maze behavior, via its metabolism to $3\alpha,5\alpha$ -THP, since inhibiting the enzymatic conversion of progesterone to $3\alpha,5\alpha$ -THP blocked the anxiolytic effect of progesterone [184]. Likewise, results from a recent study suggest that the ability of progesterone to attenuate CRF-enhanced acoustic startle response might be due to progesterone's metabolism to $3\alpha,5\alpha$ -THP, since administration of $3\alpha,5\alpha$ -THP had a similar effect, whereas use of a progestin that was not metabolized to $3\alpha,5\alpha$ -THP (i.e., medroxy-progesterone) did not [149]. While the putative modulatory role of brain versus peripheral-derived $3\alpha,5\alpha$ -THP on anxiety-related behavior is not clear, recent work has examined the effect of ligands that stimulate biosynthesis of $3\alpha,5\alpha$ -THP in adrenalectomized–gonadectomized (ADX–GDX) and intact animals [131, 185]. These ligands, which activate peripheral benzodiazepine receptors, significantly increased brain levels of $3\alpha,5\alpha$ -THP to a

greater extent in the intact versus ADX–GDX rats, yet the increase in brain 3 α ,5 α THP also was associated with a marked anti-conflict effect in the Vogel test. Thus, it is possible that peripheral sources of 3 α ,5 α THP may have a greater impact in modulating anxiety-related behavior than brain-derived 3 α ,5 α THP.

4.4.1 HPA Axis and Stress

Acute stress of many types results in the release of CRF, adrenocorticotrophic hormone (ACTH), and cortisol in humans and corticosterone in rodents (see Fig. 4.5) [186]. Corticosteroids bind to mineralocorticoid receptors (MRs) and glucocorticoid receptors (GRs), which are colocalized in brain regions important in the regulation of anxiety, such as the hippocampus, septum, and amygdala. A recent report indicated that increased corticosterone levels in rodents were highly correlated with measures of risk assessment [187]. Several animal models of anxiety have demonstrated that both MR and GR can modulate specific aspects of anxiety, as antagonists for both receptor subtypes have been shown to have anxiolytic effects [186].

GRs are found in higher concentrations in regions involved in feedback regulation of the hormonal stress response. GRs have a 10-fold lower affinity for corticosterone than MRs, becoming occupied only during stress and at the circadian peak, whereas

Figure 4.5 Various points of control for regulation of the HPA axis by neurosteroids, neurotransmitters, ACTH, glucocorticoids, and the immune system[186, 222, 224, 284–286]. A variety of stressors activate the HPA axis, which is typically observed as an increase in glucocorticoids from the adrenal cortex. Stress also produces an increase in levels of the GABAergic neurosteroids 3 α ,5 α -THP and alloTHDOC in the brain via the circulation and *de novo* synthesis. (Adapted from Nestler et al. [170].) (See color insert.)

MR is almost completely occupied under basal conditions. Since it is believed that GR action is mainly regulated by hormone level, with MR action being influenced by receptor density, endogenous corticosteroids can play an important role in the maintenance of homeostatic equilibrium via its two receptors [188, 189]. High corticosteroid levels, such as those elicited by exposure to an acute stressor, decrease the number of GRs, which in turn results in increased corticosterone secretion and feedback resistance.

One of the many neurotransmitters that can modulate HPA axis activity is the GABAergic system, as the GABAergic innervation of CRF-producing cells of the hypothalamic paraventricular nucleus (PVN) has been shown to be particularly important for the control of HPA axis activity [190]. For example, GABAergic function in the PVN was increased after ADX and was normalized when corticosteroid levels were restored [191]. A series of elegant studies recently determined that corticosterone can modulate GABAergic function in PVN neurons within hours in a mode different from that of neurosteroids (i.e., presynaptic vs. postsynaptic effect) [192]. Restraint stress was found to decrease GABAergic inhibition by 50%, suggesting that the corticosterone-induced changes in GABAergic function in the PVN also occur with natural fluctuations in this hormone level due to stress exposure.

Adding another level of complexity to regulation of the HPA axis, acute stressors and activation of the HPA axis also can increase levels of the GABAergic neurosteroids $3\alpha,5\alpha$ -THP and alloTHDOC (see Figs. 4.2 and 4.5 and Section 4.1). One possibility is that a stress-induced increase in GABAergic neurosteroids could participate in the adaptation to the stress response. Consistent with this idea, administration of $3\alpha,5\alpha$ THP reduced anxiety that was induced by CRF [193] in addition to exerting actions within the hypothalamus to dampen the activity of the HPA axis [193, 194].

4.4.2 Anxiety-Related Disorders

Alterations in HPA axis function are suggested in posttraumatic stress disorder (PTSD), as shown by a decrease in cortisol levels and increased suppression of cortisol levels with the GR agonist dexamethasone (dexamethasone suppression test, DST), suggesting enhanced sensitivity to cortisol feedback [195, 196]. Patients with PTSD also had a blunted ACTH response to CRF versus control subjects, suggesting hypersecretion of CRF [197]. Consistent with this observation, patients with combat-related PTSD had elevated levels of CRF in the cerebrospinal fluid (CSF) [198]. However, more recent work suggested that women with PTSD do not differ from traumatized subjects or non-traumatized controls in basal cortisol levels [199]. When the subjects were challenged with a dose of ACTH that had been reported to elicit cortisol responses equivalent to that seen following extreme naturalistic stressors, the cortisol responses were significantly increased in the patients with PTSD versus other subjects. An independent study determined that, following a CRF challenge dose, cortisol levels determined hourly in CSF over a 6 h period were significantly elevated in patients with PTSD compared to matched control subjects [200]. Whereas baseline DHEA levels did not differ between the patients in the study by Rasmusson et al. [199], the increase in DHEA in response to the ACTH challenge was significantly greater in the PTSD patients. The authors hypothesized that the anti-glucocorticoid properties of DHEA might antagonize glucocorticoid negative feedback within the

brain and pituitary, which would ultimately result in an increase in the adrenal capacity for cortisol release due to a facilitation of CRF or ACTH release.

CSF levels of CRF have also been shown to be elevated in patients with obsessive compulsive disorder [201], but not panic disorder [202]. However, an additional study demonstrating no difference in baseline CSF levels of CRF between control subjects and patients with generalized anxiety disorder, panic disorder, or obsessive-compulsive disorder [203] suggests that these patients did not exhibit tonic hypersecretion of CRF. Therefore, evidence for dysfunction of CRF or HPA systems in anxiety disorders has been inconsistent [204].

A recent study by Strohle and colleagues in patients with panic disorder [205] demonstrated that panic attacks induced by sodium lactate and cholecystokinin tetrapeptide were accompanied by marked decreases in circulating levels of 3α , 5α -THP and 3α , 5β -THP, with concomitant increases in the neuroactive steroid antagonist 3β , 5α -THP. Similar changes were not observed in control subjects. Baseline 3α , 5α -THP levels in these patients were increased [206], particularly in the early follicular phase of the menstrual cycle [207]. It is possible that during an induced panic attack patients with panic disorder fail to maintain compensatory increased 3α , 5α -THP levels. Therefore, neuroactive steroids may play a role in the pathophysiology of panic disorders.

Early work suggested that examination stress produced a significant increase in the density of peripheral benzodiazepine receptors (PBRs), compared to unstressed controls [208]. Although PBRs play a role in the translocation of cholesterol from the outer to the inner mitochondrial membrane [209], which represents the rate-limiting step for the synthesis of neuroactive steroids (see Fig. 4.1) [210], the physiological consequence of the increased PBR with regard to neuroactive steroid biosynthesis was not known. More recent work determined that PhD examination stress increased heart rate, blood pressure, plasma 3α , 5α -THP, and cortisol levels and the density of PBR when compared with baseline levels [211]. The increase in plasma cortisol was not correlated with the increase in PBR density, suggesting that the acute stress-induced increase in cortisol levels did not depend on rapid biosynthesis. Notably, the increase in plasma 3α , 5α -THP was significantly positively correlated with increased PBR density. Although no causal relationship can be drawn from these findings, it is possible that use of synthetic PBR agonists to enhance the synthesis of 3α , 5α -THP could be useful in the treatment of anxiety disorders [211].

A number of studies in which various animal models of anxiety were utilized demonstrated that injection of CRF into the locus ceruleus, paraventricular nucleus of the hypothalamus, BNST, and CeA produced signs and symptoms that were identical to animals in response to stress as well as those observed in patients with anxiety disorders [137, 148, 212–215]. Notably, central CRF systems, in addition to those that participate in the control of the HPA axis, contribute to affective behavior regulation [216]. In male rats, alfaxalone, the 11-keto derivative of 3α , 5α -THP, was shown to attenuate the anxiogenic behavioral effects of CRF and swim stress without reducing the CRF-induced increases in plasma ACTH [217]. Alfaxalone also inhibited the startle enhancing effects of CRF in male rats without disrupting CRF-stimulated locomotor activity [218]. At doses of 5 and 10 μg i.c.v., 3α , 5α -THP counteracted the anxiogenic action of 5 μg CRF in male rats and prevented the adrenalectomy-induced upregulation of CRF gene expression [193]. Both

progesterone and $3\alpha,5\alpha$ -THP attenuated CRF-enhanced acoustic startle, whereas the progestin medroxyprogesterone acetate enhanced CRF-induced startle [149]. Thus, CRF appears to play a significant role in anxiety-related and stress-related states that can be attenuated by GABAergic neuroactive steroids. Collectively, the data also suggest that agents acting at CRF receptors may have therapeutic value in anxiety disorders. Indeed, the development of CRF receptor antagonists as novel anxiolytics is being actively pursued (see chapter 5) [215].

For a more detailed discussion of neuroactive steroids in psychopathology and menstrual cycle-linked CNS disorders, the reader is referred to the reviews by Dubrovsky [219], and Backstrom et al., [220] and chapter 21 in volume I of this handbook.

4.4.3 Depression

Evidence suggests that stressful life events can produce hyperactivity of the HPA axis and can increase vulnerability to depression [170, 221–225]. In general, patients with major depressive disorder exhibit elevated plasma cortisol and CRF levels, with approximately 50% of patients displaying an impaired suppression of cortisol secretion after dexamethasone administration (DST test) [225]. Patients with stress-associated disorders such as depression appear to escape from glucocorticoid negative feedback, resulting in a persistent activation of the HPA axis.

Protracted social isolation in rodents produces behavioral symptoms also found in depression, in addition to producing a significant decrease in cortical $3\alpha,5\alpha$ -THP levels and a decrease in expression of the biosynthetic enzyme 5α -reductase [182]. Taken in conjunction with the finding that $3\alpha,5\alpha$ -THP has antidepressant properties [174], manipulation of neuroactive steroid biosynthesis may have therapeutic benefits. Studies in patients with unipolar depression found a 60% decrease in $3\alpha,5\alpha$ -THP content in CSF or plasma, compared to values in normal subjects [226–228]. Treatment with fluoxetine, a broad-spectrum antidepressant that inhibits serotonin reuptake, for 8–10 weeks normalized the levels of $3\alpha,5\alpha$ -THP in the depressed patients. Improvement in symptomatology and the increase in $3\alpha,5\alpha$ -THP concentrations in CSF were significantly, positively correlated in the study by Uzunova et al. [227]. It was subsequently determined that fluoxetine altered $3\alpha,5\alpha$ -THP biosynthesis by increasing the affinity of 5α -DHP for the enzyme 3α -hydroxysteroid dehydrogenase (see Fig. 4.1) [229]. Data in rats indicate that the effect of fluoxetine on $3\alpha,5\alpha$ -THP biosynthesis was rapid; significant increases in brain $3\alpha,5\alpha$ -THP levels were observed between 15 and 120 min post injection of fluoxetine [230]. This ability of fluoxetine to shift the activity of the 3α -hydroxysteroid dehydrogenase enzyme toward the reductive direction (i.e., toward the formation of $3\alpha,5\alpha$ -THP from 5α -DHP) provides evidence for a possible role of neuroactive steroids in successful antidepressant therapy.

There are massive levels of progesterone ($\sim 5 \times 10^{-7}$ M) in maternal plasma during human pregnancy near term. These levels are much greater (5- to 50-fold) than those that occur in most other pregnant mammals, including non-human primates [231]. It is therefore not surprising that the combined levels of $3\alpha,5\alpha$ -THP and $3\alpha,5\beta$ -THP approach 15 ng/mL or $\sim 5 \times 10^{-8}$ M near term (Fig. 4.6), although there are wide individual variations. There is only a very limited transfer of progesterone from maternal plasma into the fetus, but it does enter the

Figure 4.6 Combined levels of anxiolytic metabolites of progesterone, allopregnanolone, and pregnanolone, measured in 11 normal women during pregnancy. The weeks of gestation were established from last menstrual period. The levels of the anxiolytic metabolites were measured in duplicate by specific RIA after extraction of serum and separation of the individual neuroactive steroids as described by Purdy et al. [21] and Schmidt et al. [287]. (Data from R. Purdy and D. Castracane, unpublished.)

fetal circulation from the placental syncytiotrophoblast where it is synthesized and then converted in the fetus to $3\alpha,5\alpha$ -THP and its sulfate [232].

The etiology of depression in childbearing women is poorly understood, but it has been suggested that the very large changes in progesterone and its anxiolytic metabolites in the postpartum period may predispose some women to depression [233, 234]. These dramatic postpartum changes are illustrated in Fig. 4.7 as the dramatic logarithmic decrease in concentrations of progesterone, $3\alpha,5\alpha$ -THP, and $3\alpha,5\beta$ -THP in the maternal plasma of three normal women. A more detailed time profile of pregnanolone isomers in the postpartum period has been provided by Hill et al. [235]. Gilbert Evans et al. [236] have found a significant reduction in the concentrations of $3\alpha,5\alpha$ -THP plus $3\alpha,5\beta$ -THP in pregnant women with a history of postpartum depression at 36–38 weeks, regardless of their current state of depression. Their results suggest that depression history was associated with an underlying dysregulation of these neuroactive steroids.

4.4.4 Acute and Chronic Effects of Alcohol

Acute and chronic administration of alcohol also activates the HPA axis, measured by an increase in plasma corticosterone in rodents [237–241]. Elegant work by the Rivier laboratory demonstrated that i.p. or intragastric administration of alcohol produced a rapid, significant increase in plasma ACTH levels [242] and neuronal activity in the cell bodies of the PVN of the hypothalamus that express CRF and vasopressin [238, 239]. Since available *in vivo* evidence had not consistently

Figure 4.7 Logarithm of sum of micromolar concentrations (\pm standard error of the mean) of progesterone (PROG, open circles) and sum of its two anxiolytic metabolites (closed circles), allopregnanolone (5α -THPROG) and pregnanolone (5β -THPROG), obtained in the plasma from three women up to 36 h after parturition. The anxiolytic metabolites were measured by RIA as described in Fig. 4.6. Progesterone was measured by RIA in duplicate using a standard kit from ICN (Costa Mesa, CA). (Data from R.H. Purdy and D. Castracane, unpublished.)

demonstrated whether acute administration of alcohol influenced pituitary activity, independent of CRF and vasopressin, the mechanism by which ethanol stimulated the HPA axis was uncertain. However, recent findings shed some light on the specific sites of action of ethanol on the activity of the HPA axis. Specifically, i.c.v. and i.p. administration of alcohol increased the expression of proopiomelanocortin (POMC) in the anterior pituitary with a time course that corresponded to ACTH release [243]; these responses were completely abolished by immunoneutralization of CRF and vasopressin. This finding provides strong evidence that the stimulatory effect of acute alcohol administration on the HPA axis requires the release of endogenous CRF and vasopressin, rather than a direct pituitary influence of alcohol on the corticotropes.

Acute administration of anesthetics, including ethanol, also has been shown to increase plasma levels of progesterone, the parent steroid of $3\alpha,5\alpha$ -THP, in male rats [244]. This initial finding was recently extended with the demonstration that acute injection of ethanol doses ranging from 1 to 4 g/kg significantly increased cortical $3\alpha,5\alpha$ -THP levels to pharmacologically active concentrations in rats and mice [245–247]. Acute alcohol intoxication also increased plasma $3\alpha,5\alpha$ -THP levels in male and female adolescent humans [248, 249]. Due to the fact that the pharmacological profile of ethanol is similar to that of $3\alpha,5\alpha$ -THP, it has been suggested that certain behavioral effects of ethanol and $3\alpha,5\alpha$ -THP might share a GABAergic mechanism [250, 251]. Taken in conjunction with the demonstration that manipulating endogenous $3\alpha,5\alpha$ -THP levels altered specific behavioral and physiological effects of ethanol (i.e., \uparrow $3\alpha,5\alpha$ -THP, \uparrow ethanol effect; \downarrow $3\alpha,5\alpha$ -THP, \downarrow ethanol effect) [246, 252], these data suggest that an ethanol-induced increase in endogenous $3\alpha,5\alpha$ -THP levels might potentiate or prolong certain behavioral effects of ethanol via its

action at GABA_A receptors. Since additional studies demonstrated that the endocrine response to acutely administered alcohol was principally due to steroid biosynthesis in adrenal and gonadal tissue [253–255], it is possible that endogenous 3 α ,5 α -THP levels might play a role in the modulation of the excitability of the HPA axis in response to stress (see Fig. 4.5) and in the modulation of cortical 3 α ,5 α -THP concentration after ethanol injection.

Electrophysiological recordings from CA1 pyramidal neurons determined that the action of ethanol on GABA_A receptor-mediated inhibitory postsynaptic current amplitude was biphasic [256]. Initially, there was a rapid, direct effect of ethanol on GABA_A receptor activity, followed by an indirect effect that was believed to be mediated by the synthesis of 3 α ,5 α -THP. Furthermore, it has been clearly demonstrated by these electrophysiological methods that ethanol increases GABAergic transmission at both presynaptic and postsynaptic sites in rat central amygdala neurons [257], as well as altering glutamatergic transmission in this tissue [258]. This poses the possibility of neuroactive steroid action at both of these sites of neurotransmission within the amygdala.

4.4.5 Stress-Induced Drug Reinstatement

Drug relapse is a major problem in the treatment of drug addiction in humans [259]. Early work in monkeys and rodents used a reinstatement procedure as an animal model of drug relapse [260–263]. In the reinstatement model, laboratory animals initially are trained to lever press for access to drugs in operant chambers, which produces robust self-administration behavior. The drug-reinforced responding is extinguished when saline is substituted for the drug solution or when the infusion pump is disconnected (i.e., the animal stops pressing the lever and responding to the stimuli previously associated with drug delivery). During reinstatement tests, animals are given access to the levers, but the drug remains unavailable, making it possible to test for the ability of various events to reinstate drug-seeking behavior. The results from a number of laboratories have determined that the following events are extremely effective in promoting operant-reinforced responding on the lever previously associated with drug: reexposure to the drug (i.e., priming injection), acute exposure to stressful stimuli (e.g., footshock), and environmental stimuli (e.g., cues) previously associated with drug self-administration [264–268].

In the 1990s, many studies demonstrated that exposure to intermittent footshock was at least as effective as priming injections of cocaine, heroin, or nicotine and even more effective than priming injections of alcohol in promoting high levels of responding in tests of reinstatement over a range of footshock durations (10–60 min) [269–273]. Administration of CRF (0.3 and 1 μ g, i.c.v.) potently reinstated heroin-seeking behavior, whereas the CRF antagonist α -helical CRF_{9–41} (3 and 10 μ g, i.c.v.) attenuated stress-induced but not heroin-induced reinstatement [274]. Additional studies determined that ADX and corticosterone replacement did not alter footshock-induced reinstatement to alcohol [275], whereas the nonselective CRF antagonist D-Phe-CRF_{12–41} (0.3 and 1 μ g, i.c.v.) and the nonpeptide CRF₁ receptor antagonist CP-154,526 (15–30 mg/kg, subcutaneous) significantly decreased reinstatement of alcohol-, heroin-, and cocaine-seeking behavior that was induced by intermittent footshock [275, 276]. These data suggest that extra hypothalamic CRF systems are involved in stress-induced drug reinstatement behavior.

With regard to neurosteroid effects on drug reinstatement, a single study has demonstrated that priming injections of $3\alpha,5\alpha$ -THP (3 and 7.5 mg/kg, i.p.) dose dependently reinstated previously extinguished responding for ethanol but not for sucrose [277]. In contrast, conditioned stimuli reinstated previously extinguished ethanol- and sucrose-seeking behavior, suggesting that the mechanisms that subserve cue-induced reinstatement do not depend on the nature of the positive reinforcer tested. However, the fact that $3\alpha,5\alpha$ -THP selectively promoted responding for ethanol after a period of abstinence suggests that GABA_A receptor modulation may contribute to the processes involved in reinstatement of ethanol-seeking behavior.

Notably, several neuroactive steroids also modulate ethanol self-administration behavior. The initial study determined that $3\alpha,5\alpha$ -THP significantly increased ethanol-reinforced operant responding in male rats [278] by enhancing responses during the initial run of a 30-min operant session. A subsequent study determined that $3\alpha,5\alpha$ -THP selectively enhanced ethanol-reinforced operant responding when a sucrose solution was concurrently available [279], suggesting specificity for $3\alpha,5\alpha$ -THP in modulating ethanol self-administration in male rats. Consistent with these findings, $3\alpha,5\alpha$ -THP dose dependently increased ethanol preference drinking during the first hour of 2-h limited-access sessions in male mice [280, 280a]. In contrast to the results with $3\alpha,5\alpha$ -THP, epipregnanolone and a novel neuroactive steroid with a 3α -carboxyl group ($3\alpha,5\beta$ -20-oxo-pregnane-3-carboxylic acid, termed PCA) dose dependently reduced operant ethanol self-administration in male rats [281]. The opposite effect of epipregnanolone and PCA on ethanol self-administration may be related to different inhibitory actions of these compounds on either GABA_A or NMDA receptors, respectively [282, 283]. Thus, dual modulation of inhibitory and excitatory neurotransmitter systems by certain neuroactive steroids may provide a novel therapeutic potential for modifying the reinforcing effects of addictive drugs.

4.5 CONCLUSIONS AND OUTLOOK

There has been an exponential increase in basic science and clinical investigations of neuroactive steroids in the last two decades. Methodological advances in the specificity, sensitivity, and accuracy of measurement of nonconjugated neuroactive steroids are still continuing. The chemical nature of the “sulfate-like” esters of PREG and DHEA in brain has yet to be elucidated, even though these esters are predominant in mammalian blood. Since anesthetic neuroactive steroids such as alfaxalone were introduced five decades ago, there has been a continuing interest in the development of other synthetic neuroactive steroids for the clinical treatment of neurological disorders, including stress and anxiety. Additionally, neuroactive steroids have been linked to pathogenesis in menstrual cycle-linked disorders of the CNS.

Several thousand synthetic steroids have been assayed for their interactions as allosteric modulators of neurotransmitter systems. New compounds with unusual properties continue to be reported. Yet, in our opinion, universal recognition of the neurophysiological and neuropharmacological importance of neuroactive steroids awaits definitive demonstration of their clinical importance and therapeutic advantage.

ACKNOWLEDGMENTS

This is publication number 17678-NP from The Scripps Research Institute. This work was supported by U.S. National Institutes of Health grants AA06420, AA12439, and AA10760 from the National Institute on Alcohol Abuse and Alcoholism and by the U.S. Department of Veterans Affairs (DAF). The immobilization experiment described in Fig. 4.2 was performed in the laboratory of Nobuyoshi Hagino at the University of Texas Health Sciences Center, San Antonio, TX. The samples of plasma from pregnant women used to generate the data shown in Figs. 4.6 and 4.7 were generously provided by V. Daniel Castracane at Texas University Health Sciences Center, Amarillo, TX. The radioimmunoassays used to generate the data in Figs. 4.2, 4.6 and 4.7 were performed by Perry Moore at the Southwest Foundation for Biomedical Research, San Antonio, TX, under a contract from the National Institute of Mental Health. We gratefully acknowledge the editorial contributions of Elizabeth Gordon, Michael Arends, Mellany Santos, Eric Zorrilla, Dewleen Baker, and Mathew Ford and helpful conversations with collaborators John Crabbe and Tamara Phillips as well as invaluable assistance from members of the Finn Laboratory on various aspects of this work.

5.1 INTRODUCTION

The corticotropin-releasing factor (CRF) system is widely accepted as the primary mediator of an organism's response to stress. CRF is one of a number of neurohormones synthesized in discrete hypothalamic nuclei where in response to a stressor is secreted into the portal vasculature where it acts directly at the pituitary. At the pituitary, and more specifically at the anterior pituitary, CRF binds to cognate receptors resulting in the release of the proopiomelanocortin-derived peptide adrenocorticotrophic hormone (ACTH). This in turn acts at the adrenal gland to secrete glucocorticoids, and these steroids feed back at the level of the hypothalamus and the anterior pituitary to attenuate the release of CRF and ACTH, respectively. This hormone loop is known as the hypothalamic–pituitary–adrenal (HPA) axis and is tightly regulated in mediating the stress response. In addition to its endocrine effects, CRF is widely distributed, synthesized, and secreted from extrahypothalamic

sites within the central nervous system (CNS) acting on higher centers of the brain where it mediates the appropriate response of the organism to various physical and psychological stressors.

Although the modern concept that hypothalamic secretions were the key mediators of the stress response dates back to the works of Sir Geoffrey Harris and Hans Selye in the early 1950s [1, 2], it was the independent determination from the experiments of Guillemin and Rosenberg [3] and Saffran and Schally [4] that provided the first direct evidence of a hypothalamic factor (CRF) that was responsible, under stressful situations, for regulating the production of ACTH. The identity of this specific factor, however, was not discovered until 30 years later when Vale and colleagues [5] reported the isolation, characterization, synthesis, and *in vitro* and *in vivo* biological activities of CRF from sheep hypothalamus. Once this peptide was characterized, evidence began to accumulate that this stress hormone may play a major role in human affective disorders. Nemeroff and colleagues made one of the first observations implicating this system in depression by demonstrating that the cerebrospinal fluid (CSF) of depressed patients contained elevated levels of the CRF peptide itself, suggesting a hypersecretion of this hormone in the brain during this disease [6]. At the same time, two groups independently demonstrated that in depressed individuals the ACTH response to systemic administration of CRF was blunted, suggesting a downregulation of the system [7–9], and a positive correlation was observed between CSF concentrations of CRF and the degree of post-dexamethasone suppression of plasma cortisol [10]. These data taken together indicated the tight control of a system whereby elevated levels of CRF in the CNS could cause the downregulation or desensitization of the receptors at the pituitary, thereby causing a blunting of the ACTH response upon exogenous administration of CRF. Further corroboration of this hypothesis was presented by the findings that in suicide victims CRF receptor binding sites were significantly decreased in postmortem frontal cortical tissue, again consistent with the mechanism of elevated levels of CRF in brain causing a homologous downregulation of CRF receptors [11].

Examination of CRF in detail presented further evidence that this system plays a key role in the manifestation of anxiety and depression. Levels of CRF in the CNS of depressed individuals who had undergone successful treatment paradigms were found to be altered in a direction consistent with the hypothesis that elevated levels of CRF were manifesting the disease symptomatology. For example, when CRF was measured in the CSF of depressed individuals before and after successful electroshock convulsive therapy (ECT), the elevated levels of CRF in the CSF was found to decrease following ECT and corresponded to patient improvement in mood [12]. Another study, performed on 24 patients suffering from major depression and treated for six to eight weeks with antidepressants, interestingly found that although no differences in the CSF levels of CRF were observed between pre- and posttreatment, despite clinical improvement, those patients who did not relapse in the following six months had a significant reduction in CSF concentrations of CRF while those that relapsed did not. These findings suggest that the hyperactivity of CRF in the CNS may predispose patients to relapse following treatment and are consistent with the findings of a higher risk of relapse in patients that exhibit elevated levels of cortisol following concomitant administration of the CRF/dexamethasone suppression test [13]. Furthermore, while the simple measurement of CRF peptide in the brain may not accurately reflect the hyperactivity of the system in these disorders, clinical

studies to date are in agreement that CRF levels in the CSF generally decrease in parallel with clinical recovery regardless of the treatment paradigm used [14, 15].

More than a decade later, the receptors for this neurohormone were identified and cloned from a variety of species, including human. The ability to look biochemically at the cloned human receptor accelerated the identification and characterization of nonpeptide small molecules that could block these receptors and paved the way for the development of novel therapeutics for disorders associated with a dysregulated stress axis, including anxiety and depression. This chapter provides a brief overview of the CRF system, including the known ligands and receptor subtypes, and details the different interactions between the ligands (both peptide and nonpeptide) and these receptors. With the relatively recent discovery of nonpeptide antagonists for the CRF system, the similarities and differences between the receptor/ligand interactions will be examined and the preliminary evidence and potential for their utility as anxiolytics and antidepressants will be presented.

5.2 CRF RECEPTOR/LIGAND FAMILY

Since the discovery of ovine CRF from the sheep hypothalamus, other functional CRF peptides have been identified from many species, including rat [16], human [17], goat [18], cow [19], pig [20], suckerfish (urotensin-I, isolated from the urophysis extract of the sucker (teleost) fish *Catostomus commersoni* [21, 22]), and xenopus (sauvagine isolated from a skin extract of the South American tree frog *Phyllomedusa sauvegei* [23, 24]). All of these peptides demonstrated the ability to cause the secretion of ACTH from primary cultures of rat anterior pituitary cells [25]. Initially, urotensin-I was thought to subserve the role of CRF in the fish; however, the discovery of two independent CRF genes in this species [26] prompted many laboratories to begin searching for the presence of other CRF-like molecules in mammals. In 1995, with the aid of immunocytochemical methodologies, a urotensin-like molecule was isolated from the Edinger–Westphal nucleus of the rat brain which had high homology (63% sequence identity) to urotensin-I [27]. This new peptide, termed urocortin, was cloned, synthesized, and found to stimulate the secretion of ACTH both in vitro and in vivo. The human homolog of urocortin was subsequently identified by the cloning of its messenger RNA (mRNA) from a human genomic brain library and localized to human chromosome 2 [28]. These initial findings became the basis for the discovery of a family of mammalian urocortin peptides which, as will be described below, have distinct distributions and pharmacological profiles but whose precise relevance to human physiology or pathophysiology is not yet completely understood.

CRF and its related peptides mediate their actions through high-affinity binding sites in various peripheral and central tissues. In addition, a high-affinity soluble binding site exists, the CRF binding protein, which is expressed predominantly in the brain and pituitary and is presumed to modulate the activity of CRF itself [29]. Both the natural peptides and the close analog peptides have been radiolabeled and used in radioligand binding and receptor autoradiographic studies of the distribution of CRF receptors and their role(s) in physiological processes. There have been numerous publications that have described the radioligand binding characteristics of CRF receptors using those available radioligands in a variety of

tissues (for a review see [30–33]). The receptors for CRF exist as two distinct subtypes encoded by separate genes and have been termed CRF₁ and CRF₂. Both receptors belong to the class B family of G-protein-coupled receptors (GPCRs), which includes receptors for secretin, vasoactive intestinal peptide (VIP), calcitonin, and glucagon, among others. CRF₁ receptors positively regulate the accumulation of cyclic adenosine monophosphate (cAMP) in response to CRF in both heterologously expressed systems and native tissues from brain and periphery and are therefore coupled to G_s as the major signal transduction mechanism [34, 35]. The CRF₂ receptor has also been shown to couple through G_s and stimulate the production of cAMP, but thus far only in heterologously expressed cell lines containing the human, rat, or mouse forms [36–38].

5.2.1 Ligands for CRF Receptor Family

Since the discovery of ovine CRF, many peptides from multiple species have been discovered that play similar functional roles as described above. In addition to urocortin 1 (UCN1), two other mammalian peptides have been identified from the mouse and human termed urocortin 2 (UCN2) and urocortin 3 (UCN3) [39, 40]. In the human, these same peptides have been identified as stresscopin (SCP) and stresscopin-related peptide (SRP) [41]. The species homology between mouse and human is 76% for SRP/UCN2 and 90% for SCP/UCN3 and these peptides share approximately 30–40% homology with rat/human (r/h) CRF and urocortin. (for a review see [42]). While UCN1 has equal affinity for both CRF receptor subtypes, UCN2 and UCN3 are selective for the CRF₂ receptor subtype and have little or no affinity for the CRF binding protein (described in detail below).

CRF and the related urocortins have been localized to a variety of tissues within the body. The literature is replete with articles detailing the localization and distribution of CRF and the urocortins both from the mRNA and the protein levels. While a full description is beyond the scope of this chapter, briefly, within the CNS, CRF is widely distributed with the highest levels evident in the hypothalamus, amygdala, cortical regions, and cerebellum (reviewed in [31, 43–47]). In general, the distributions of CRF and the urocortins are remarkably nonoverlapping with one exception and a common localization to hypothalamic structures. UCN1 demonstrates the highest levels of expression in regions such as the Edinger–Westphal nucleus, substantia nigra, lateral superior olive, dorsal raphe nucleus, and hypothalamus [27, 48–50]. UCN2 is also discretely localized to hypothalamic nuclei, specifically the paraventricular, supraoptic, and arcuate nuclei as well as in the brain stem [40]. UCN3 is primarily localized to the hypothalamus and more specifically in the preoptic and paraventricular nuclei. It is also highly expressed in medial amygdala, lateral septum (indicating an association with the CRF₂ receptor), and bed nucleus of the stria terminalis [51]. In addition, these peptides have been localized in a variety of peripheral tissues, including the skin and skeletal muscle [52], human heart and kidney [53], and the colon, suggesting a role for stress-induced gastrointestinal (GI) function [54–56].

To date, there are no known endogenous physiological antagonists for the CRF receptor system, however; various truncations of agonist peptides, with deletions of the first 8–11 N-terminal amino acids, have resulted in potent peptide antagonists, both selective and nonselective with respect to their affinities at the CRF₁ and CRF₂

receptor subtypes. These peptides have shed new light not only on understanding the physiology of the CRF system but also for the elucidation of the discrete interactions of the peptide/ligand complex. As with the agonist peptides either deletions of the C-terminal amino acids or simple deamidation of the carboxy terminus renders these peptides essentially inactive at CRF receptors, suggesting that at some level the binding requirements for these ligands have some similarities between the two receptor subtypes. Deletions of the agonist peptides or modifications in the N-terminus, however, have successfully identified potent and functional receptor antagonists that are both selective and nonselective for the CRF receptor subtypes. Peptides such as α -helical CRF(9–41) [57], d-PheCRF(12–41) [58], and astressin [59] were synthesized and found to be potent functional antagonists at both the CRF₁ and CRF₂ receptor subtypes. Antisauvagine-30 [60], an N terminally truncated form of sauvagine, and the more recent cyclized astressin-2B [61] are two peptides that have approximately 400- to 500-fold selectivity for the CRF₂ receptor over the CRF₁ receptor, and these peptides have been recently used to begin dissecting out specific roles of the CRF₂ receptor subtype in a variety of in vivo studies [62, 63]. As will be discussed below, the peptide interactions with the receptors lie largely with the extracellular N-terminal domain of the receptors, and it is precisely the composition of the N-terminus of the peptides that confers agonist activity. This point is illustrated elegantly by the recent studies examining the interactions of the peptide antagonist astressin and the expressed soluble form of the N-terminus of the CRF₁ receptor [64].

5.2.2 Subtypes and Distribution of CRF Receptor

The current understanding of the subfamily of CRF receptors encompasses two receptor subtypes termed CRF₁ and CRF₂ receptors, with the CRF₂ receptor existing in three identified splice variant isoforms (CRF_{2(a)}, CRF_{2(b)}, and CRF_{2(c)}). Prior to the cloning and elucidation of the subtypes of CRF receptors, the labeled agonists [¹²⁵I]r/hCRF and [¹²⁵I]ovine(o) CRF were used to elucidate the binding characteristics and anatomical distribution of CRF receptors in the brain, and many publications exist describing the binding characteristics of these prototypical labeled compounds (for review see [30–33]). Indeed, early drug discovery efforts utilized these ligands in native brain homogenate preparations (typically rat frontal cortex or cerebellar tissues) to identify nonpeptide molecules as potential antagonists. Fortunately, these early pharmacological characterizations and drug discovery efforts were largely unaffected by the discovery of a second family member (the CRF₂ receptor) by virtue of the fact that the prototypical endogenous peptides [¹²⁵I]r/hCRF and [¹²⁵I]oCRF have lower affinity for the CRF₂ receptor subtype (10–100 nM), making them essentially in vitro selective tools for the CRF₁ receptor under the conditions in which they were being used. The subsequent radiolabeling of the amphibian peptide sauvagine (from frog skin, *P. sauvagei* [23]), which has high affinity for both the CRF₁ and CRF₂ receptor subtypes, allowed for the first time the discrimination of CRF₁ and CRF₂ receptor pharmacology and distribution [65].

The CRF₁ receptor was first cloned from a human corticotropic tumor and characterized as a 415-amino-acid receptor belonging to the class B subfamily of GPCRs with a characteristically large N-terminus, linked to seven putative trans-membrane domains terminating with an intracellular C-terminal tail and reported

along with an alternatively spliced form of which included a 29-amino-acid insert in the first intracellular loop (Fig. 5.1) [66]. This was shortly followed by the cloning of the rat form of this receptor by the same group [67]. Following the cloning and characterization of the CRF₁ receptor the second subtype of this family was identified and termed the CRF₂ receptor [37] and was also subsequently identified from a variety of species [36–38]. This subtype had approximately 71% identity with the CRF₁ receptor and was shown to exist as three independent splice variants differing from each other only at the extreme N-terminal end (see Fig. 5.1). The chromosomal mapping of the human CRF₂ gene has also been determined and has been localized to chromosome 7p21–p15 [68]. As with any rapidly expanding family of proteins, consistency of molecular nomenclature is difficult to maintain. The literature unfortunately contains a number of different designations for this family of receptors, including CRF-RA [67] and PC-CRF [36, 69] for the CRF₁ receptor; CRF_{2 α} [37] for the CRF_{2(a)} receptor; CRF-RB [67], CRF_{2 β} [37], and HM-CRF [36] for the CRF_{2(b)} receptor; and CRF_{2 γ} [70] for the CRF_{2(c)} receptor. In an attempt to maintain some consistency with other GPCR families of receptors, a nomenclature for these subtypes has recently been proposed according to the International Union of Basic and Clinical Pharmacology (IUPHAR) convention for the naming of receptors, and these receptors should be referred to hereafter as CRF₁, CRF_{2(a)}, CRF_{2(b)}, and CRF_{2(c)} receptors [71].

Compared to the CRF₁ receptor, the CRF_{2(a)} receptor is a 411-amino-acid protein with the typical glycosylation sites in the N-terminal domain. The CRF_{2(b)} receptor, which has been cloned from rat, mouse, and human, contains 431 amino acids and differs from the 411-amino-acid CRF_{2(a)} isoform in that the first 34 amino acids in the N-terminal extracellular domain are replaced by a unique sequence 54 amino acids in length [37, 72]. The CRF_{2(c)} receptor has thus far only been identified in the amygdala of the human brain [70]. This splice variant uses yet a different 5' alternative exon for its amino terminus and replaces the first 34-amino-acid sequence of the CRF_{2(a)} receptor with a unique 20-amino-acid sequence (see Fig. 5.1). Very recently a soluble splice variant of the mouse CRF_{2(a)} receptor has been identified and characterized. This soluble protein appears to localize in the same discrete anatomical brain regions of the mouse brain and may represent yet another mechanism through which this system can modulate the activity of its endogenous agonists [73].

There have also been a number of splice variants for the CRF₁ receptor reported in the literature; however, the physiological significance of these variants still remains to be determined. Besides the first 29-amino-acid variant first described in the initial pituitary tumor library described above, a second splice variant for the CRF₁ receptor (CRF_{1 γ}) derived from human hypothalamus has been reported where a large portion of the N-terminal domain is deleted. This protein, however, has lower affinity for agonists and appears to be weakly functional when expressed in mammalian cell lines [74]. Finally, a third splice variant identified from human pregnant myometrium (CRF_{1 δ}) contains a deletion of 14 amino acids in the C-terminus of the seventh transmembrane domain. On heterologous expression of this receptor, it was found that while binding of agonist ligands was largely unaffected, this receptor could not couple through G proteins and was therefore functionally inactive [75]. While these receptor splice variants offer insight into the structure and functional conformations of the CRF₁ receptor, their in vivo

physiological relevance will have to await further mRNA and protein expression determinations in native tissues.

Many studies have described in great detail the anatomical distribution of the CRF receptor subtypes and isoforms in a variety of species using both receptor autoradiographic studies with [125 I]sauvagine or [125 I]oCRF and in situ hybridization studies using probes that are both subtype specific and isoform selective (reviewed in great detail in [76–80]). The highest density of CRF₁ receptors exists in the pituitary gland, where CRF₁ expression clustered on corticotropes related to its effects on the release of ACTH from the anterior lobe of the pituitary [77]. High levels of CRF₁ receptors have been localized in brain to the cerebral cortical areas, amygdala, and hippocampus in rodents and also in hypothalamus and amygdala in nonhuman primates (for review see [77, 80]). There are also a number of peripheral sites to which CRF receptors have been localized, including adrenals, and throughout the immune and reproductive systems where levels of CRF₁ mRNA have been localized in the testis and ovary [81–83]. A major peripheral site of high expression for this receptor is the GI tract [84–86]. Localization studies have suggested a distinct functional role for this protein in gut function and motility and compliment the reported actions of CRF and related endogenous peptides that have been examined in detail [63, 87, 88] and mimic the effects of stress on gastric and colonic motility [89, 90]. In fact, the concept of stress-induced pathophysiology in the gut and the role of the CRF receptors in mediating this pathology is currently generating a great deal of interest for drug discovery. The potential utility of CRF receptor antagonists for GI stress disorders such as irritable bowel syndrome have been recently reviewed [91–94].

The localization and distribution of the CRF₂ receptor are quite different and more varied within the CNS and across species than the CRF₁ receptor. Unlike the similarities in CNS distribution of the CRF₁ receptor between species, the CRF₂ receptor exhibits more species differences in the localization of receptor subtypes between rodent, nonhuman primate, and human tissues. Within the rat brain, CRF_{2(a)} receptor expression is generally confined to subcortical structures, including the lateral septal region, the bed nucleus of the stria terminalis, the amygdaloid area, and the olfactory bulb [77], whereas in higher order species such as human and nonhuman primates the CRF_{2(a)} receptor is distributed in high densities across the cortical regions as well as the brain structures described in rodents [77]. While the role of the CRF₂ receptor in anxiety disorders still requires some clarification, some recent studies have begun to demonstrate that at least the CRF_{2(a)} receptor may well facilitate the manifestation of anxiety. The lateral septum, by virtue of widespread reciprocal connections throughout the brain, is implicated in a variety of physiological processes playing a central role in classical limbic circuitry and thus potentially integrating a variety of emotional conditions including fear and aggression. In fact, it has recently been demonstrated that acute antagonism of the CRF₂ receptor in the lateral septum using the nonselective peptide antagonists produced a specific reduction in stress-induced behavior. This effect was not produced by the administration of selective CRF₁ receptor antagonists into this brain region [95]. In addition, it has been shown that selective peptide antagonists for the CRF₂ receptor administered intracerebroventricularly in mice were able to attenuate CRF or UCN2-induced increases in acoustic startle, suggesting in this model that the CRF₂ receptor may participate in the progression of the anxiety response [96]. In addition, CRF₂ receptor knockout studies have demonstrated that mice lacking the

CRF₂ receptor gene exhibit anxiety-like effects as well as a hypersensitivity to stress, further suggesting a role for this subtype in the overall response to stress [97]. Key to the understanding of the role of this receptor in anxiety or depression, of course, will be the development of selective nonpeptide receptor antagonists and their evaluation in primate models of disease. With these tools, a solid understanding of the role of this receptor subtype can be defined and the CRF_{2(a)} receptor may yet represent an additional target for the development of novel anxiolytics.

The CRF_{2(b)} splice form is localized primarily on nonneuronal elements, such as the choroid plexus of the ventricular system and cerebral arterioles. In the periphery, CRF_{2(b)} mRNA is expressed at high levels in both cardiac and skeletal muscle with lower levels evident in both lung and intestine [77, 98]. Most recently the CRF_{2(b)} receptor has been localized in the human cardiovascular system where the ligands UCN2 and UCN3 have been shown to cause vasodilation [99, 100]. Interestingly, these effects, if shown to be able to counteract the pressor effects of centrally mediated CRF₁ receptor effects of CRF and urocortin, may define a tight regulation of stress-induced cardiovascular changes [100]. The CRF_{2(c)} isoform has yet to be identified in the rodent; however, reverse transcriptase polymerase chain reaction (RT-PCR) analysis of human brain mRNA demonstrated expression in septum, amygdala, hippocampus, and frontal cortex [70]. A full characterization of the CRF_{2(c)} subtype and the role it may play in physiology or pathophysiology still remains to be determined. As with the CRF₁ receptor, the CRF₂ receptor is also highly expressed and localized to the GI tract [56, 84] and there have been recent reports demonstrating clear efficacy of the selective CRF₂ agonists UCN2 and UCN3 on GI motility and pain responses [101], further suggesting that this receptor subtype may be involved in the manifestation of stress- or anxiety-induced pathophysiology.

5.3 PEPTIDE LIGAND PHARMACOLOGY OF CRF₁ AND CRF₂ RECEPTORS

As defined above, the CRF receptor and ligand system is unusual in that the receptors are activated by multiple endogenous ligands (CRF, UCN1, UCN2, and UCN3 [42, 71, 102]). The receptors have been shown to couple to multiple G proteins and intracellular signaling pathways [103, 104] (reviewed in [105, 106]), but in general the most common signaling pathway is stimulation of cAMP production through activation of the G_s G protein. Peptide selectivity for the receptors has been assessed by measuring stimulation of cAMP accumulation. For the mammalian receptors overexpressed in cultured cell systems, CRF itself is moderately selective for CRF₁ over CRF₂ receptors [36, 37, 41, 65, 107–110], UCN1 is nonselective for the two subtypes [39–41, 108], and UCN2 and UCN3 are selective for the CRF₂ over the CRF₁ receptor [39–41, 109]. Interestingly, these peptides do not demonstrate any appreciable differences in activation potency when assessed at the three splice variants of the CRF₂ receptor (CRF_{2(a)}, CRF_{2(b)}, and CRF_{2(c)}) [70, 111]. A similar CRF₁/CRF₂ receptor selectivity profile has been demonstrated for receptors expressed endogenously (i.e., at normal physiological levels) in tissues and receptor-expressing cell lines [39, 41, 112–115]. For example, the pharmacological rank-order profile of peptide agonists at CRF₁ receptors in the AtT20 mouse corticotrope tumor cell line and CRF_{2(b)} receptors in A7r5 rat smooth muscle cells is similar to that in

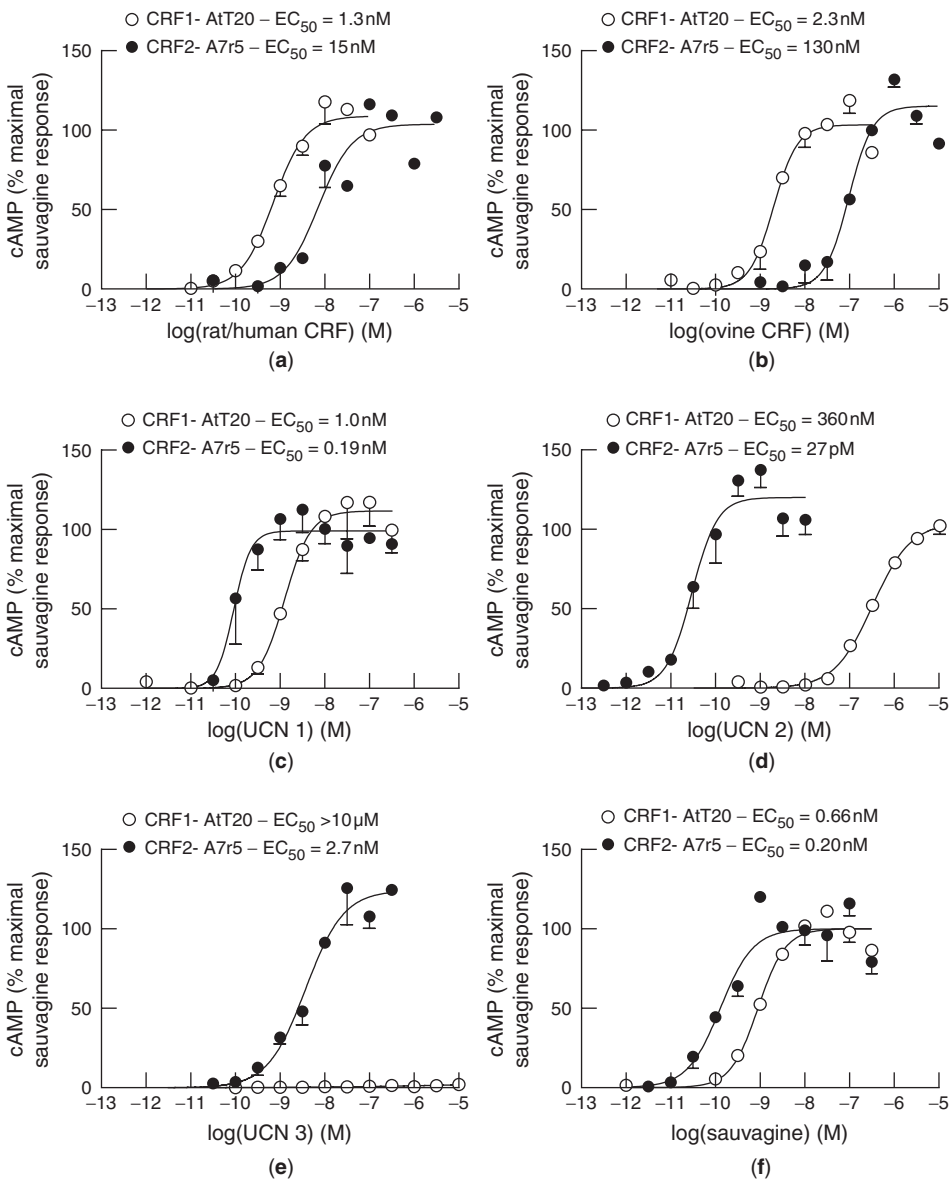

Figure 5.2 Stimulation of cAMP accumulation via CRF receptors expressed endogenously in model cell lines by CRF-related peptides. cAMP accumulation was measured in the mouse AtT20 corticotrope cell line, which expresses CRF₁, and the rat A7r5 aortic smooth muscle cell line, expressing CRF_{2(b)}. EC_{50} values are the mean of three experiments. (Data compiled from [116].)

heterologously expressed receptor systems (Fig. 5.2) [116]. This validation is important because receptor overexpression can distort pharmacological behavior of agonist ligands, for example resulting in enhancement of agonist potency [reduction of median effective concentration (EC_{50})] or enhancement of efficacy (enhanced E_{\max}).

As described above, synthetic peptide antagonists have been developed, by N-terminal truncation and amino acid substitution of the endogenous peptide agonists [57, 59–61, 109, 117, 118]. N-terminal truncation of CRF [57, 109], UCN1 [119], UCN2 [109], and sauvagine [60, 61] results in a loss of receptor activation but retention of detectable receptor binding. Certain critical amino acid substitutions of these truncated peptides increase affinity for one or both CRF receptors [57, 59–61]. For example, the nonselective antagonist astressin is a CRF(12–41) fragment with substitutions designed to enhance affinity (L-Phe¹¹ to D-Phe¹¹) and a lactam between residues 30 and 33 that stabilizes α -helical structure in the C-terminal portion of the peptide [61]. The extent of α helicity correlates well with the antagonist potency [57, 117]. Recently even shorter C-terminal analogs of astressin (12 amino acids, residues 30–41) have been reported that possess comparable potency to the parent peptide [118]. N-terminal truncation of sauvagine together with certain substitutions yielded the CRF₂-selective antagonists antisauvagine-30 [60] and astressin₂-B [61]. In addition to the truncated forms of agonists that yield antagonists, numerous peptide chimeras have also been developed by combining sequence fragments of the different endogenous peptides. Examples include cortagine, an agonist selective for the CRF₁ receptor over the CRF₂ receptor [110].

Peptide ligand binding to CRF₁ and CRF₂ receptors has been measured using radiolabeled peptides. Both receptor subtypes are readily labeled by [¹²⁵I]sauvagine [65, 116, 120, 121], an agonist, and [¹²⁵I]astressin [121, 122], an antagonist. Other radioligands include radiolabeled UCN1 [122–124] for CRF₁ and CRF₂ receptors, [¹²⁵I]oCRF for selectively labeling CRF₁ [30, 124, 125], and [¹²⁵I]antisauvagine-30 for selectively labeling CRF₂ [126]. Ligand binding affinity for G-protein-coupled receptors is dependent on the conformational state of the receptor. In general, agonists bind with higher affinity to the G-protein-coupled state (RG state) than the uncoupled receptor (R state), whereas antagonist binding does not discriminate between these states [127, 128]. Taking this differential binding pharmacology into account can be important for identifying receptor subtypes in tissues and for understanding ligand binding mechanisms (see below). For CRF receptors the RG state can be selectively labeled using a radiolabeled agonist [30, 65, 116, 120, 121, 124, 125] such as [¹²⁵I]sauvagine [116, 121]. The R state can be generated using guanosine triphosphate (GTP) or its nonhydrolyzable analogs (such as GTP γ S). These guanine nucleotides bind the α subunit of heterotrimeric G proteins, leading to the breakdown of the receptor–G protein complex [129]. The resulting R state of CRF receptors can be labeled by the antagonist [¹²⁵I]astressin [116, 121, 122]. For the CRF₁ receptor, peptide agonists bind with much higher affinity to the RG state than to the R state (Fig. 5.3, Table 5.1) and vary from 77-fold for UCN1 to 690-fold for oCRF [121]. This finding suggests uncoupling the G protein from its receptor substantially reduces binding of peptide agonists to the CRF₁ receptor, implying agonism results at least in part from ligand discriminating the RG state over the R state. By contrast, peptide agonist binding to the CRF₂ receptor is much less sensitive to the conformational state of the receptor with a change of 1.2-fold higher affinity for RG for UCN1 to a 6.5-fold difference for UCN2 (Fig. 5.3, Table 5.1 [116]). This finding suggests that for the CRF₂ receptor uncoupling receptor from G protein does not strongly affect peptide agonist binding, a hypothesis supported by the only slight reduction of [¹²⁵I]sauvagine binding produced by GTP γ S (Fig. 5.3i) [65, 116, 120, 126]. Peptide antagonist affinity for both receptors was unaffected by

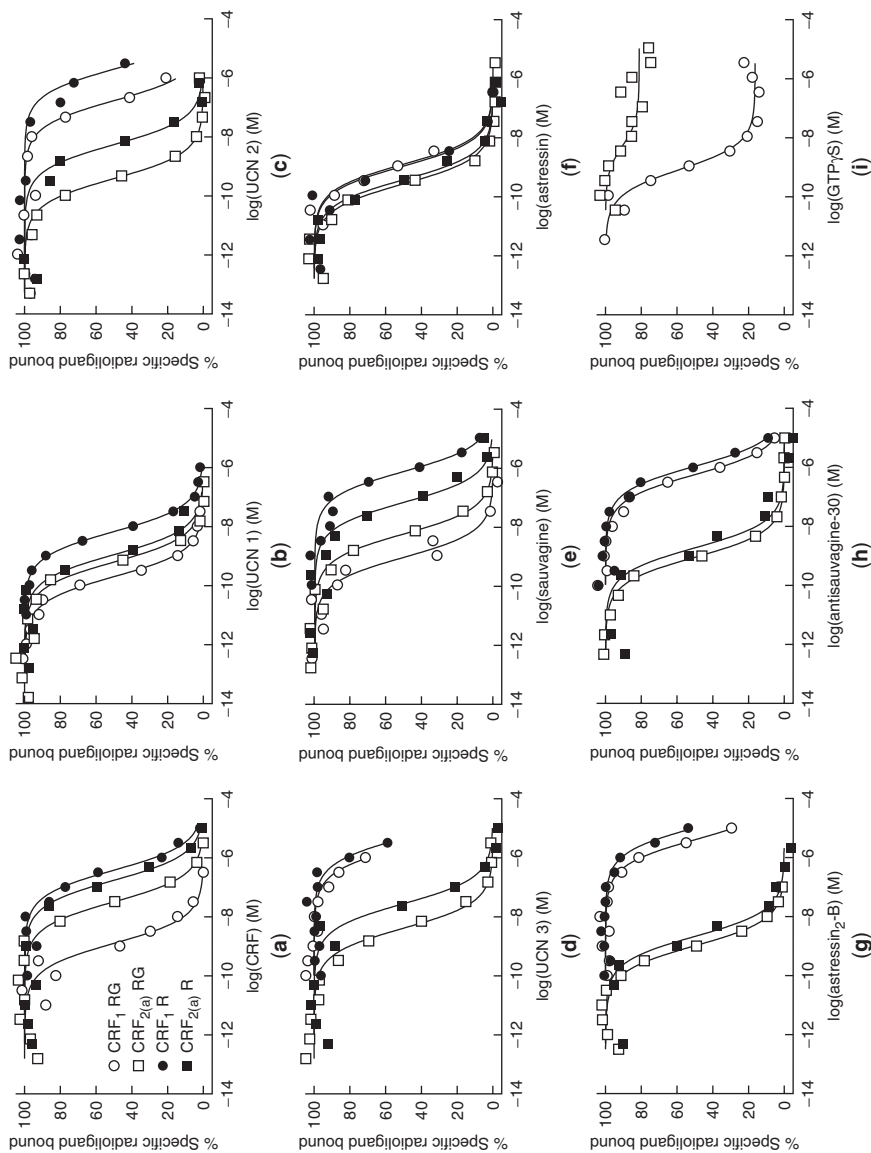

Figure 5.3 Peptide ligand affinity for different receptor states of CRF receptors. Peptide ligand affinity can be dependent on the state of the receptor. Peptide affinity for the G-protein-coupled state (RG state) of the human CRF_1 and $\text{CRF}_{2(a)}$ receptors can be measured by competition against a radiolabeled peptide agonist ($[^{125}\text{I}]\text{sauvagine}$). Peptide affinity for the receptor uncoupled from G protein (R state) was measured in competition versus a radiolabeled antagonist peptide ($[^{125}\text{I}]\text{astressin}$) in the presence of $\text{GTP}\gamma\text{S}$. This guanine nucleotide binds the α subunit of heterotrimeric G proteins, leading to the breakdown of the receptor-G protein complex. Data for the human CRF_1 receptor are for this receptor in membranes prepared from LtK^- mouse fibroblasts [121]. Data for the human $\text{CRF}_{2(a)}$ receptor are for this receptor in Chinese hamster ovary cell membranes. (Data compiled from [116, 121].)

TABLE 5.1 Peptide Ligand Affinity (nM) for R and RG States of Human CRF₁ and CRF_{2(a)} Receptors^{a,b}

Peptide Ligand	RG State		R State	
	CRF ₁ K _i (nM)	CRF ₂ K _i (nM)	CRF ₁ K _i (nM)	CRF ₂ K _i (nM)
r/hCRF	0.30	19	270	38
oCRF	0.29	150	200	320
hUCN1	0.039	0.27	3.0	0.33
hUCN2	130	0.17	640	1.1
hUCN3	> 1000	1.3	> 1000	6.6
Sauvagine	0.45	2.6	230	11
Astressin	0.43	0.15	0.67	0.11
Antisauvagine-30	150	0.29	340	0.40
Astressin ₂ -B	950	0.49	4200	0.57

^bPeptide ligand affinity for G-protein-coupled (RG) receptor state was measured in competition versus a radiolabeled agonist peptide ([¹²⁵I]sauvagine) for human CRF₁ or CRF_{2(a)} receptors expressed in mammalian cells (L + k⁺ cells [121] and CHO cells, respectively [116]). Peptide affinity for the receptor uncoupled from G protein (R state) was measured in competition versus a radiolabeled antagonist peptide ([¹²⁵I]astressin) in the presence of GTPγS. This guanine nucleotide binds the α subunit of heterotrimeric G proteins, leading to the breakdown of the receptor–G protein complex.

the conformational state of the receptor (Figs. 5.3f–h, Table 5.1 [108, 116, 121, 122, 124, 126]), implying antagonism results from a lack of discrimination between RG and R states.

Peptide ligand selectivity for binding one CRF receptor over the other has historically been determined using radiolabeled agonists [65, 108, 116, 120, 121, 123], particularly [¹²⁵I]sauvagine. Under these conditions, affinity estimates for receptors are likely those for the RG state of CRF₁ and CRF₂ receptors. Selectivity in binding the RG state approximately correlates with selectivity in functional cAMP accumulation experiments: in the binding assays, r/hCRF is selective for CRF₁ over CRF₂ (63-fold for cloned human CRF₁ and CRF_{2(a)} receptors; Table 5.1, Fig. 5.3a); oCRF is more CRF₁ selective (520-fold, Table 5.1); UCN1 and sauvagine are nonselective (Table 5.1, Figs. 5.3b,e); UCN2 and UCN3 are strongly CRF₂ selective (760-fold and > 770-fold, respectively, Table 5.1, Figs. 5.3c,d); astressin is a nonselective antagonist (Table 5.1, Fig. 5.3f); and astressin₂-B and antisauvagine-30 are CRF₂-selective antagonists (510-fold and 1900-fold, respectively, Table 5.1, Figs. 5.3g,h) [39, 60, 108, 109, 116, 121, 122]. This selectivity profile has been demonstrated for CRF receptors expressed endogenously in tissues (e.g., cerebellum for CRF₁ [121] and olfactory bulb for CRF₂ [116]). A different selectivity profile is manifest for the uncoupled R state of the receptor. In this conformation, CRF peptides are no longer selective (Table 5.1, Fig. 5.3a) and UCN1 and sauvagine are slightly selective for CRF₂ over CRF₁ receptors (9.0-fold and 21-fold, respectively, Table 5.1, Figs. 5.3b,e) [116]. Therefore, in identifying the receptor subtype in tissues it is important to consider the nature of the conformational state labeled by the specific radioligand used. The use of agonist radioligands is recommended, enabling comparison with a wealth of historical data.

5.3.1 Mechanisms of Peptide Ligand Binding to CRF₁ and CRF₂ Receptors

The molecular mechanisms of peptide ligand binding to CRF receptors have been investigated using point-mutated receptors [130–139], chimeric receptors [116, 130–134, 138, 140, 141], receptor fragments [64, 119, 139, 140, 142–146], receptor–ligand crosslinking [136, 147], and nuclear magnetic resonance (NMR) chemical shift perturbation [139]. These studies have indicated a low-resolution binding orientation termed the “two-domain” model, also demonstrated for other class B GPCRs. In this mechanism, the carboxyl terminal portion of the peptides interacts with the N-terminal domain (N-domain) of the receptors, and the amino terminal portion of the peptide binds the receptors’ juxtamembrane domain (J domain, comprising the transmembrane helices and intervening loops). Binding determinants in both receptor domains have been identified using receptor mutants and chimeric receptors (Fig. 5.1). Peptide ligands interact with both N- and J-domain fragments expressed in isolation (Fig. 5.4). The carboxyl terminal fragments of CRF and sauvagine

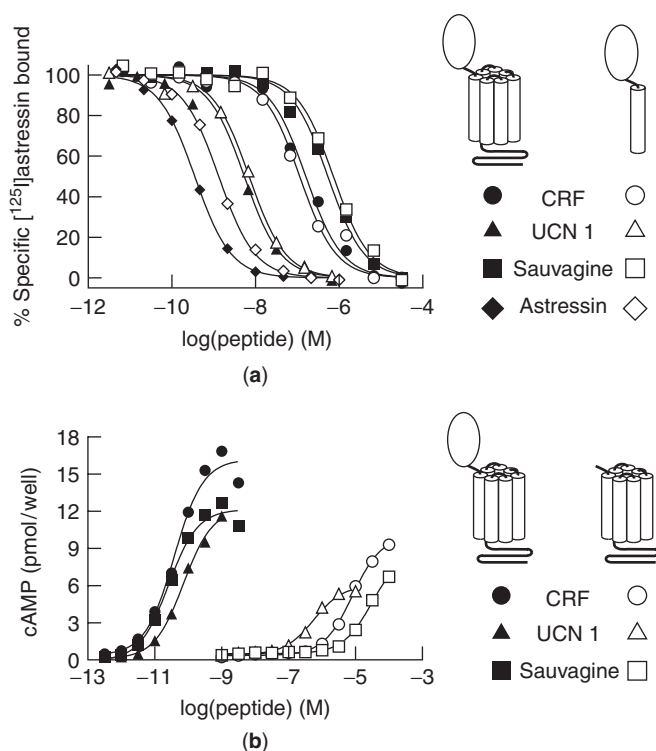

Figure 5.4 Interaction of peptide ligands with (a) N domain and (b) J domain of CRF₁ receptor. (a) Peptide ligand interaction with the N domain was measured by inhibition of [¹²⁵I]astressin binding to the N domain fused to the single-membrane-spanning α helix of the activinII-B receptor [140, 146]. Peptide affinity for the whole receptor was measured by inhibition of [¹²⁵I]astressin binding in the presence of GTP γ S to uncouple receptor from G protein. (b) Peptide ligand interaction with the J domain was measured by stimulation of cAMP accumulation via a J-domain fragment [146]. Note that peptide potency on the J domain is dramatically reduced compared with the whole receptor. The peptides did not affect cAMP accumulation in nontransfected cells [146]. (Data compiled from [146].)

(astressin and antisauvagine-30, respectively) bind with high affinity to N-domain fragments of CRF₁ and CRF₂ receptors [64, 140, 144–146] (Fig. 5.4a). Modifying the carboxyl terminal residue of CRF by deamidation eliminates detectable binding to the N-domain fragment of the CRF₁ receptor but does not affect interaction with the J-domain fragment [146]. Tethering the N-terminal 16 amino acids of CRF to the J domain of the CRF₁ receptor results in receptor activation [143]. Receptor–ligand crosslinking, utilizing the CRF₁ receptor and peptides with photoactivatable side chains, indicated residue 16 of sauvagine crosslinks L257 in the second extracellular loop [136]; the extreme N-terminus and residue 12 of UCN1 bind the second extracellular loop; and residues 35 and 40 of UCN1 bind the C-terminal region of the N domain [147].

The molecular mechanism has been evaluated to a higher resolution for the interaction of astressin with the N domain, utilizing structural data for peptide and the N domain [139]. NMR, circular dichroism, and other analytical studies of CRF-related peptide structure indicate transient-to-stable formation of α helix within the C-terminal region [57, 59, 117, 118, 148, 149], depending on the experimental conditions and peptide studied. An NMR structure of a soluble N domain of the mouse CRF_{2(b)} receptor was recently reported [139]. A central core contains a salt-bridge sandwiched between aromatic side chains surrounded by conserved residues. Two antiparallel β sheets are interconnected by the core. Loop regions of poorly resolved structure are adjacent to the structured core region. The tertiary structure is stabilized by three disulfide bonds (C45–C70, C60–C103, and C84–C118 for the mouse CRF₂ receptor). These three cysteines are conserved within CRF receptors and other class B GPCRs [64, 139, 144, 150]. NMR chemical-shift perturbation within the N domain upon binding astressin [139] indicates residues in and around the structured core are direct or indirect binding determinants (I67, G68, T69, G90, I91, K92, N94, A99, Y100, E102, R112, V113, N114, Y115, and S116). These residues are highly conserved within CRF receptor subtypes and species variants, suggesting a common molecular mechanism of peptide ligand binding to the N domain [139]. Mutation of I67 and R112 of the CRF_{2(b)} receptor reduces affinity of astressin 120- and 6.5-fold, respectively [139]. Mutation of residues analogous to K92 and A99 of the CRF_{2(b)} receptor in the CRF₁ receptor also reduces peptide ligand affinity [132]. These data can be rationalized by a molecular model of astressin interaction with the CRF_{2(b)} N domain, in which the carboxyl terminal portion of astressin binds as an α helix to a broad, slightly concave surface within the structured core region [139]. Proposed interactions between an astressin and the mouse CRF_{2(b)} receptor include electrostatic interaction between E39 and R112 and between K35 and E119 and hydrophobic interaction between L37 and Y115 and between I41 and P120 [139].

Less is known about the molecular interactions of the amino-terminal portion of the peptide and the J domain of the receptor. The solution structure of the amino-terminal portion of the peptide is not well characterized, and nothing is presently known of the receptor-bound structure of this region of the peptide. In addition the structure of the J domain of CRF receptors has not been determined. The transmembrane helices of this region have been modeled by homology using the crystal structure of bovine rhodopsin as a template, but the predictive utility of these models might be limited owing to the very low amino acid sequence homology between CRF receptors (class B GPCRs) and rhodopsin (a class A GPCR) [139]. The

only obvious common feature between class A and B GPCRs is the potential disulfide bond between transmembrane type 3 (TM3) and extracellular loop 2, although evolutionary trace analysis has suggested a small number of other common hydrophobic amino acid residues within the transmembrane domains [151, 152]. Peptide binding determinants within the J domain are located within the predicted extracellular loops and toward the predicted extracellular ends of transmembrane helices (Fig. 5.1). These results suggest the amino-terminal portion of peptide ligand binds to the extracellular face of the J domain of CRF receptors, an arrangement that has also been suggested for other class B GPCRs [150]. Interestingly, circumstantial evidence suggests N terminally truncated CRF and sauvagine analogs can interact with the J domain of the receptors. Astressin, a 12–41 residue analog of CRF, blocks activation of a CRF₁ J-domain fragment by CRF, albeit at high concentrations [146]. Additionally, this peptide binds with 10-fold higher affinity to the whole CRF₁ receptor than an N-domain receptor, suggesting additional binding determinants within the J domain [146]. Shorter C-terminal CRF analogs (residues 30–41, peptides 19 and 20 of [118]) bind with similar affinity to the whole receptor and the N domain, suggesting residues within the 12–29 region of astressin bind the J domain of the CRF₁ receptor [153]. Finally, analysis of chimeric CRF₁/CRF₂ receptors indicated that the J domain acts as a selectivity determinant for CRF₂-selective antisauvagine-30 and astressin₂-B (11–40 analogs of sauvagine), suggesting these peptides interact with the J domain of the CRF₂ receptor [116]. Taken together these findings suggest peptide antagonists can bind the J domain of CRF₁ and CRF₂ receptors, possibly through interactions with amino-terminal residues of the peptides.

The J domain of the CRF₁ receptor is involved in ligand binding and conformational changes of the receptor that lead to receptor activation and desensitization. Peptide agonists stimulate cAMP accumulation via a J-domain fragment (Fig. 5.4b) [146] and the amino-terminal portion of CRF activates a J-domain fragment when tethered to this receptor [143]. In addition, full-length peptide agonist binding to the CRF₁ receptor is markedly reduced by GTP γ S, whereas residue 12–41 analogs of CRF (e.g., astressin) are unaffected (see above). This finding suggests interactions of residues within the 1–11 sequence with the J domain are sensitive to G-protein coupling to the receptor. Peptides that appear to only bind the N domain (peptides 19 and 20 in [118]) do not activate the CRF₁ receptor, suggesting ligand interaction with the N domain is not required for receptor activation. These short fragments also fail to affect CRF₁ receptor internalization, whereas full-length CRF robustly stimulates internalization [153]. This result provides circumstantial evidence that ligand interaction with the J domain but not the N domain stimulates CRF₁ receptor internalization. Interestingly, astressin also stimulates CRF₁ receptor internalization, an unusual effect of an antagonist ligand [153]. This effect is mediated through receptor interaction of the 12–29 region of the peptide [153], likely through binding the J domain (see above). The receptor conformation mediating astressin-induced receptor internalization appears distinct from that for CRF; the latter ligand promotes receptor phosphorylation and arrestin recruitment to the receptor, whereas the former ligand does not [153].

The strength of peptide agonist interaction for each of the N and J domains has been quantified for the CRF₁ receptor using N- and J-domain fragments. UCN1 binds with high affinity (approximately 5 nM) to the CRF₁ N domain expressed in isolation as a membrane-proximal protein (expressed as a fusion with the single

membrane-spanning α helix of the activinII-B receptor) [64, 140, 146]. CRF and sauvagine bind with lower affinity to the N domain (approximately 50 and 500 nM, respectively [64, 140, 146]). Similar data were obtained with a soluble CRF₁ N-domain fragment [64, 119, 144, 145]. Peptide ligand affinity for the membrane-anchored N-domain fragment has been compared with that for the whole CRF₁ receptor, enabling quantification of the contribution of the N domain to overall ligand affinity. In this comparison the G-protein-uncoupled (R) state of the full-length CRF₁ receptor was used, since the N domain on the extracellular membrane surface is incapable of coupling to G protein on the intracellular membrane surface. For the CRF₁ receptor these experiments demonstrated that peptide agonist affinity for the N domain is only slightly stronger (less than twofold) on the full-length, G-protein-uncoupled CRF₁ receptor than on the membrane-anchored N domain fragment, indicating the N domain contributes almost all the ligand binding energy at the R state [140, 144, 145]. Direct peptide binding to the J domain of the CRF₁ receptor is extremely weak—on the isolated J-domain fragment, peptide agonist EC₅₀ for stimulating cAMP production was four to six orders of magnitude higher than EC₅₀ for the whole receptor (Fig. 5.4b) [146]. Taken together these findings suggest a sequential mass action binding model for agonist peptides [146] in which peptide first binds the N domain of the CRF₁ receptor with moderate to high affinity (depending on the peptide agonist) (Fig. 5.5a). This interaction provides an “affinity trap” that enormously increases the local concentration of peptide in the vicinity of the J domain, allowing the weak J domain interaction to occur (Fig. 5.5a). This concentrating effect of N-domain binding enables significant ligand interaction to occur with the J domain at physiological levels of ligand. Ligand interaction with the J domain promotes receptor activation and stimulation of G-protein coupling leading to intracellular signaling (Fig. 5.5a). Reciprocally, G-protein coupling to the CRF₁ receptor increases the affinity of peptide agonists by 49- to 690-fold [121], likely through increasing peptide affinity for the J domain [146]. Taken together, these findings suggest a quantitative model for the CRF₁ receptor in which (1) peptide agonists bind with moderate to high affinity for the N domain (100 nM for CRF); (2) peptide binding to the J domain weakly stabilizes binding at the R state of the receptor (<2-fold for CRF); and (3) peptide binding to the J domain is strongly stabilized by G-protein coupling to the receptor (> 100-fold for CRF).

Similar techniques have been applied to estimate peptide agonist affinity for the CRF₂ receptor. UCN1 and UCN2 bind with high affinity to a membrane-anchored CRF_{2(b)} receptor N domain (5.4 and 16 nM, respectively), whereas UCN3, CRF, and sauvagine are less potent (> 200, 79, and > 200 nM, respectively) [145]. Similar data were obtained with a soluble CRF_{2(b)} receptor fragment [145]. Peptide agonist affinity for the whole CRF_{2(b)} receptor (R state) was significantly higher than affinity for the isolated J domain (from 2.9-fold for CRF to 33-fold for UCN2) [145], suggesting an appreciable contribution of the J domain to peptide agonist affinity at the R state (in contrast to the CRF₁ receptor for which the J domain contributed minimally to peptide agonist affinity at the R state). G-protein coupling to the CRF_{2(a)} or CRF_{2(b)} receptor only weakly stabilizes peptide agonist binding (e.g., 1.2- to 6.5-fold for CRF_{2(a)}). Within the context of the two-domain model, these results imply that, first, peptide agonists bind with moderate to high affinity to the N domain of the CRF₂ receptor (16 nM for UCN2); second, binding is moderately stabilized through peptide interaction with the J domain of the R state (33-fold for UCN2); and third,

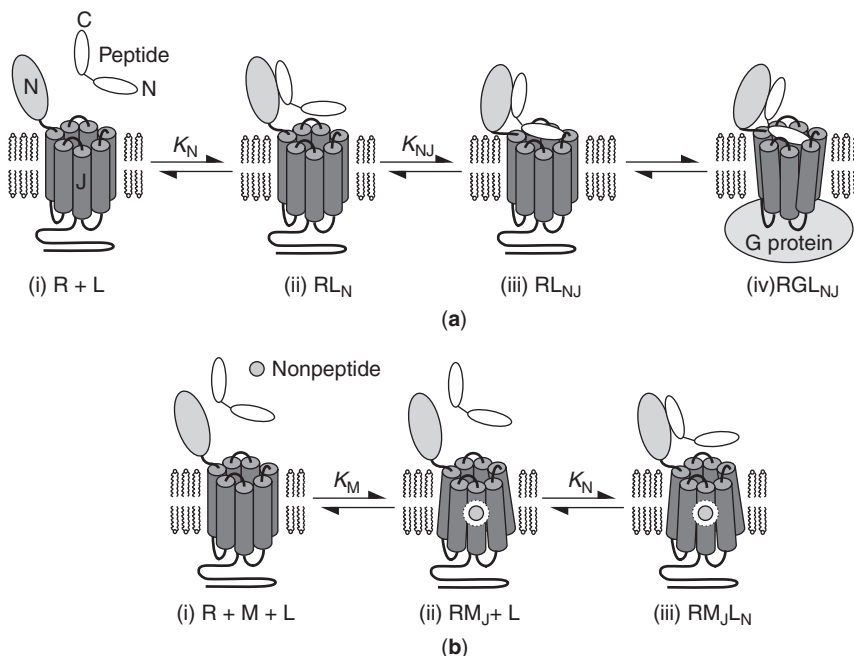

Figure 5.5 Binding models of peptide and nonpeptide ligand interaction with CRF receptors. (See [146] for a detailed description of these models.) (a) Binding model of peptide ligand interaction with CRF_1 and CRF_2 receptors. (i) The C-terminal region of the peptide (L) binds the N domain of the receptor (R) forming RL_N . (ii) This interaction enormously increases the local concentration of the N-terminal peptide region in the vicinity of the J domain, allowing (iii) their weak interaction to occur, forming RL_{NJ} . (iv) J-domain peptide binding increases receptor interaction with G protein, and reciprocally G-protein binding enhances J-domain affinity for peptide ligand. (b) Nonpeptide binding and antagonism model for CRF_1 receptor. (i) Nonpeptide ligand (M, small circle) binds within the J domain, forming RM_J . (ii) This interaction causes a change within the CRF_1 receptor that impedes peptide binding to its sites on the J domain. By blocking peptide–J domain interaction, the nonpeptide antagonist blocks peptide-stimulated receptor signaling because peptide–J domain interaction is required for G-protein activation. (iii) Nonpeptide ligand binding to the J domain does not prevent peptide interaction with the N domain, so the RM_JL_N complex can form. (Reproduced with permission from *Drug Discovery Today* [150].)

G-protein coupling to the receptor weakly enhances peptide agonist binding (6.5-fold for UCN2). Compared with the CRF_1 receptor (see above), the J domain appears to provide more binding energy for the CRF_2 receptor (at the R state), whereas G-protein coupling stabilizes binding less. The molecular basis of this difference between the two receptors remains to be determined.

Finally the strength of peptide antagonist interaction for N and J domains has been assessed. For both CRF_1 and $CRF_{2(b)}$ receptors astressin binds with high affinity to N-domain fragments (approximately 1 nM). Surprisingly, astressin affinity for the whole receptor is an order-of-magnitude higher for both CRF_1 and $CRF_{2(b)}$ receptors [145, 146], suggesting astressin binding is appreciably stabilized through interaction with the J domain. In addition, the J domain is a selectivity determinant of the CRF_2 -selective antagonists antisauvagine-30 and astressin₂-B, shown using

chimeric CRF₁/CRF₂ receptors [116]. Peptide antagonist binding is unaffected by receptor–G protein interaction [116, 121, 122]. These findings suggest peptide antagonists bind with high affinity to the N domain, with binding moderately stabilized through interaction with the J domain and with G-protein binding to the receptor having no effect.

5.4 NONPEPTIDE LIGANDS FOR CRF₁ RECEPTORS

Antagonism of central CRF₁ receptors has been rationalized as a potential next-generation treatment for anxiety and depression [154–157]. Since peptide antagonists generally possess poor pharmacokinetics (poor oral bioavailability, rapid clearance, and minimal brain penetration) and lack CRF₁ receptor selectivity, attempts have been made to develop small, orally bioavailable, brain-penetrating, CRF₁-selective nonpeptide antagonists. Numerous low-molecular-weight ligands have been developed that potently bind and antagonize the CRF₁ receptor (examples in Fig. 5.6; reviewed in detail in [156, 158, 159]). The large majority of these ligands comprise a central heterocyclic core (examples include the monocyclic SSR125543A [160, 161], the bicyclic antalarmin [162], and tricyclic NBI 35965 [163, 164]; Fig. 5.6), a “top” alkyl or branched alkyl side chain, and a “bottom” substituted aromatic ring. Regardless of the core composition, there is an essential requirement for a hydrogen bond acceptor, separated from the bottom aromatic group by a one-atom linker (e.g., SSR125543A) or by a two-atom linker (e.g., antalarmin) (see Fig. 5.6). Most, if not all, known nonpeptide antagonists display considerable selectivity for the CRF₁ receptor over the CRF₂ receptor (for a comprehensive review on structures see [156, 157]). This selectivity, combined with reasonable pharmacokinetics, has rendered compounds such as these exceptionally useful for evaluating the physiological and potential therapeutic roles of the CRF₁ receptor in animal models and, as described below, has been initially examined in an open label phase IIA clinical trial in major depressive disorder [165].

5.4.1 Mechanism of Nonpeptide Ligand Interaction with CRF₁ Receptor

The mechanism of nonpeptide ligand binding to the CRF₁ receptor has been investigated using receptor fragments [143, 146], receptor chimeras and mutagenesis [130], and quantitative analysis of ligand binding data [163, 166]. Nonpeptide antagonists bind the J domain, predominantly if not exclusively: Nonpeptide radioligand affinity for a J-domain fragment is not significantly different from that for the whole receptor and nonpeptide antagonist fully blocks peptide-stimulated cAMP accumulation via the J-domain fragment [146]. Constitutive activation of a J-domain fragment tethered to the N-terminal region of CRF is blocked by the nonpeptide antagonist antalarmin [143]. CRF₁/CRF₂ receptor chimeras identified TM3 and TM5 as selectivity determinants for selective nonpeptide antagonist with the CRF₁ receptor [130]. Exchange of two residues of the CRF₁ receptor for the corresponding residues of the CRF₂ receptor resulted in reduced nonpeptide ligand binding (H199 V in TM3 and M276I in TM5; Fig. 5.1) [130].

Nonpeptide antagonist likely binds regions within the J domain that are distinct from those for peptide ligand. The two mutations of the CRF₁ receptor implicated in

nonpeptide ligand binding did not affect peptide ligand binding [130]. In addition these determinants are within the predicted transmembrane bundle (Fig. 5.1), whereas peptide ligand binding determinants have been identified principally in the extracellular loop regions of the J domain (Fig. 5.1). In addition, nonpeptide versus peptide ligand binding data display diagnostic features implying nonpeptide ligand allosterically regulates peptide ligand binding, and vice versa: Nonpeptide ligands modulate peptide radioligand dissociation from the CRF₁ receptor, and peptide ligands accelerate nonpeptide radioligand dissociation [163]. In addition peptide ligands only partially inhibit nonpeptide radioligand binding at equilibrium [163, 166]. An interesting difference was observed between the allosteric effect at G-protein-coupled and G-protein-uncoupled CRF₁ receptor states. At the R state, the allosteric effect between peptide and nonpeptide ligand binding was slight. NBI 35965 binding to the receptor reduced sauvagine affinity by only 3.0-fold. In other words, sauvagine affinity for the NBI 35965-bound receptor was 690 nM compared with 230 nM for the free receptor). In contrast, at the RG state NBI 35965 binding reduced sauvagine affinity by 180-fold.

All of these observations can be explained by the model presented in Fig 5.5b and have been described in detail [146]. In this model, nonpeptide ligand binds to sites within the transmembrane region of the J domain, distinct from the sites bound by peptide ligand (Fig. 5.5b). Nonpeptide ligand binding to this region produces a change in the receptor that impedes peptide binding to its sites on the J domain. This allosteric effect blocks peptide-stimulated signaling, since J domain interaction is required for peptide agonism (see above). However, this allosteric effect does not affect peptide binding to the N domain of the receptor (Fig. 5.5b). This model can explain why the allosteric effect is greater at the RG state than at the R state. At the RG state the J domain contributes much more binding energy for peptide ligand interaction, so blocking this interaction with nonpeptide ligand substantially reduces peptide binding affinity. At the R state the J domain contributes much less peptide binding energy, so blocking this interaction only marginally reduces peptide binding. Overall this binding model retrospectively rationalizes nonpeptide-versus-peptide binding data, explains the antagonist action of the compounds, and could be prospectively useful in the future development of nonpeptide ligands.

5.5 POTENTIAL FOR THERAPEUTIC INTERVENTION IN ANXIETY AND DEPRESSION

During the course of examining the role of the CRF system in disorders such as anxiety and depression, a number of preclinical studies have suggested that anxiety-related disorders such as generalized anxiety disorder or panic disorder, while independent syndromes, share some clinical and biological characteristics with major depression. In addition to the circumstantial evidence presented above from clinical studies monitoring the regulation of the CRF system in various disease and treatment paradigms, there have been a great many experimental studies performed in animal models supporting the role of this system in the manifestation of anxiety- or depression-like behaviors. It is not surprising that the human disorders of anxiety and depression are difficult to model in animals. However, animal models have been widely used focusing on specific symptoms involving fear and/or fearful responses in

animals that are correlated to the inappropriate responses to mildly stressful stimuli exhibited in human anxiety. For example, the findings that CRF itself has central, behavioral and arousal properties that are characteristic of other anxiogenic compounds have been well documented preclinically and relate directly to the hyperarousal that defines anxiety disorders [167, 168]. In panic disorder, a role for CRF has been suggested by the observations again of a blunted ACTH response in these patients compared to normal individuals [169, 170]. The blunted ACTH response in panic disorder patients to exogenous CRF most likely reflects processes occurring above the level of the hypothalamus and related to a central hypersecretion of CRF. In a recent preclinical study, CRF-induced deficits in prepulse inhibition (PPI) in rats were reversed by pharmacological blockade with CRF receptor antagonists. The CRF-induced deficit in animals is similar to the disruption of PPI observed in patients with panic disorder where the CRF system may also be overactive [171]. Thus, by modeling some of the physiological characteristics of a disorder, it is possible to examine the mechanisms that may underlie a specific pathophysiology. There have been a number of excellent reviews detailing the myriad animal models that have been used to dissect the precise effects and regulation of CRF in stress-related behaviors [156, 172–175].

The majority, if not all, of the small-molecule CRF receptor antagonists that have been described are primarily selective for the CRF₁ receptor subtype. The few molecules that have appeared in the literature claiming CRF₂ selectivity have been at best weak inhibitors of function at the CRF₂ receptor subtype. The efforts to further develop these compounds have focused on improving their physicochemical and pharmacokinetic properties to maximize in vivo efficacy. Nonpeptide small molecules have demonstrated efficacy in a variety of rodent models of anxiety, including changes in exploratory behavior, a measure of innate fearfulness [160, 176, 177] social interaction (anxiety) stressful situations [177–181], conditioned fear responses [182–184], and acoustic startle responses [96, 185, 186]. In addition to the rodent studies, these molecules have also demonstrated efficacy in many nonhuman primate models of anxiety. For example, both antalarmin and DMP-904 (Fig. 5.6) reduced stereotypic fear responses and decreased measures of anxiety in the human intruder stress paradigm in rhesus monkey while, in addition, significantly attenuating HPA activation and the stress-induced increase in CSF CRF [187, 188]. Chronic oral administration of antalarmin in male rhesus monkeys was also demonstrated to attenuate the stress associated with social separation in these animals [189]. Finally, CRF₁ receptor antagonists have been demonstrated to block the stress-induced visceral hyperalgesia and colonic motility in rats [190], suggesting that these molecules may also have utility in stress- or anxiety-related GI disorders [91, 94]. A thorough evaluation of the current CRF₁ receptor antagonist small molecules and their potential utility in anxiety disorders has recently been published [191].

Despite the heroic efforts expended by the pharmaceutical industry in discovering novel chemical structures that interact with the CRF receptor system, there has only been one single clinical study published in the literature describing the effects of a CRF₁ receptor antagonist in depression. In this open label non-placebo-controlled phase IIA study conducted at the Max Planck Institute of Psychiatry, Munich, the pyrazolopyrimidine R121919 (NBI 30775) was found to be well tolerated in 20 patients following a 30-day, dose escalation paradigm up to 80 mg. This compound demonstrated a significant reduction in both the Hamilton depression and anxiety

Figure 5.6 Chemical structure of nonpeptide antagonists for CRF₁ receptor. Detailed reviews of CRF₁ nonpeptide ligands can be found in [156, 158, 159].

scales HAM-D and HAM-A across the treatment period without affecting either basal HPA activity or significant blunting of an exogenously administered CRF-induced ACTH response [165]. Furthermore, this molecule was found to improve sleep-EEG patterns in both human and rat [192, 193] and in a very recent study demonstrated that this treatment did not affect weight gain or plasma leptin levels in this group of depressed individuals [194]. Although in this small open label trial the compound did not demonstrate any untoward effects in the patient population [165, 194, 195], this particular compound caused some reversible liver enzyme elevations that precluded further clinical development. Nevertheless, this initial study has provided significant support for the use of CRF₁ receptor antagonists in the treatment of depression- or anxiety-related disorders. More importantly, this study suggested that it would be possible to separate the central efficacy of CRF₁ receptor blockade from the potential peripheral side effects of rendering the HPA axis unresponsive [195].

5.6 CONCLUSIONS

The discovery of selective CRF₁ receptor antagonists has completed the first steps required in the development of novel therapeutics for stress-related disease. These newly characterized tools have in turn led to the refinement and expansion of the initial hypotheses and have identified a tangible goal of producing selective molecules

that will target specific CRF-mediated behavior and physiology. While a preclinical “proof of principle” has been established whereby blockade of this system has demonstrated clear and precise functional benefits, the definitive studies in human disease have not yet been possible. Nonetheless, with the importance of this system in physiology and pathophysiology and the global efforts of academic and pharmaceutical researchers, there is little doubt that safe and selective molecules for this family of receptors will soon become available and eventually lead to some exciting novel therapeutic opportunities for neuropsychiatric and stress-related diseases. The CRF system is positioned to offer an alternative treatment option, and should the hypothesis that the cause of these disorders is manifested through an underlying overactivity of the stress system be confirmed, CRF receptor antagonists may well be the beginning of the next generation of antidepressant therapies with a novel mechanism of action.

6.1 INTRODUCTION

Obsessive-compulsive disorder (OCD) is an anxiety disorder characterized by the presence of unwanted, senseless, intrusive, and distressing thoughts, urges, and images (obsessions) and/or repetitive behaviors (compulsions). These are generally recognized as senseless by the patient. The disorder is relatively common, affecting 2–3% of the population [1, 2]. The content of these thoughts and behaviors is often related to fear of danger to self or others; contamination concerns are particularly frequent. At least half of OCD patients have their onset before the age of 15 [3], and there is evidence (reviewed below) that early-onset patients differ somewhat in comorbidity and underlying neurobiology.

The majority (over 70%) of OCD patients have other comorbid disorders [3, 4]. The pattern of comorbidity is of great interest, as early-onset patients differ in that movement disorders such as Tourette's disorder (TD) or chronic motor tics are strongly comorbid, as is attention-deficit hyperactivity disorder (ADHD) [5, 6]. Comorbid patterns are rather nonspecific for adult-onset OCD cases but include both bipolar disorder and schizophrenia. A subgroup of childhood-onset cases is believed to have onset of OCD in relation to infection with group A β -hemolytic streptococcus, presenting a parallel condition to that of Sydenham's chorea [7, 8].

While OCD is classified as an anxiety disorder in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), it is given a separate chapter here as the clinical phenomenology, drug treatment response, family studies, and brain imaging data support a separate neurobiological classification for this disorder and a distinct neuropharmacological profile as well. OCD is considered a major cause of disability worldwide [9]; in spite of this, most treatment research is relatively recent with the bulk carried out in the past two decades.

This chapter presents a selective review on the neurobiology, genetics, and neuropharmacology of OCD. For a more general recent clinically oriented review of the diagnosis and treatment of this fascinating syndrome, see Jenike (2004) [10]. As is evident from this chapter, there have been significant advances in the past two decades, but there remain major opportunities for more specific understanding of this complex and probably heterogeneous illness and its treatment.

6.2 NEUROBIOLOGY

Despite the considerable interest and surge of recent work in this area, the biological basis for OCD is unknown. Clinical phenomenology has provided some important clues to the underlying neurobiology of this disorder. For example, there are striking comorbid clinical associations between OCD or OCD-like phenomena and known brain disorders, typically those involving the motor system, which led to the hypothesis that OCD is a basal ganglia disorder. These observations are not new. In his original 1885 description of basal ganglia syndromes, Gilles de la Tourette described children with senseless rituals and tormenting obsessive thoughts associated with the tics and other movements of the syndrome that bears his name. Osler, in his 1894 monograph *On Chorea and Choreiform Affections*, describes cases with chorea and classical obsessions and compulsions [11]. The initial model of OCD [12–14] formulated a frontal-striatal circuit that is dysregulated in OCD. Research on

the motor system involving the planning of complex actions has proved to be particularly pertinent to OCD and most productive for clinical and brain imaging studies over time. The group of childhood-onset cases that appear to have onset of OCD in relation to group A β -hemolytic streptococcus infection provides another example of a Sydenham's chorea-like movement disorder associated with OCD and suggest a possible autoimmune subgroup [7, 15]. In spite of research implicating abnormal activity in cortical-subcortical circuitry, it is still not clear which aspects of these abnormalities are correlates and which are underlying causes of OCD. As the imaging literature has expanded, the proposed circuitry of OCD has become more complex, as discussed more fully below (and see Figs. 6.1 and 6.2 below).

6.2.1 Brain Imaging Studies of OCD

6.2.1.1 Structural Studies. Brain imaging studies have been the most important source of data concerning underlying brain abnormalities in OCD. Initial anatomic neuroimaging studies using computerized tomography (CT) and anatomic brain magnetic resonance imaging (MRI) found increased ventricular volumes in a pediatric sample [16] and smaller caudate volumes in male adolescents with childhood-onset OCD [17]. MRI studies have generally found enlarged ventricular volumes, but basal ganglia volumes have been variously reported as both increased and decreased [18, 19]. Increased thalamic volumes have also been found in drug-naïve patients [20]. The most convincing lesion studies involving OCD are by far the reports of OCD onset in relation to basal ganglia lesions secondary to stroke (e.g., [21]). The variability in these volumetric findings may reflect heterogeneity in the OCD population, possibly due to differences between childhood- and later-onset populations. The latter group has been most consistent with respect to basal ganglia and orbital frontal cortex (OFC) reduction [19, 22].

Figure 6.1 Anatomic schematic of OCD neural circuitry. (From [43].)

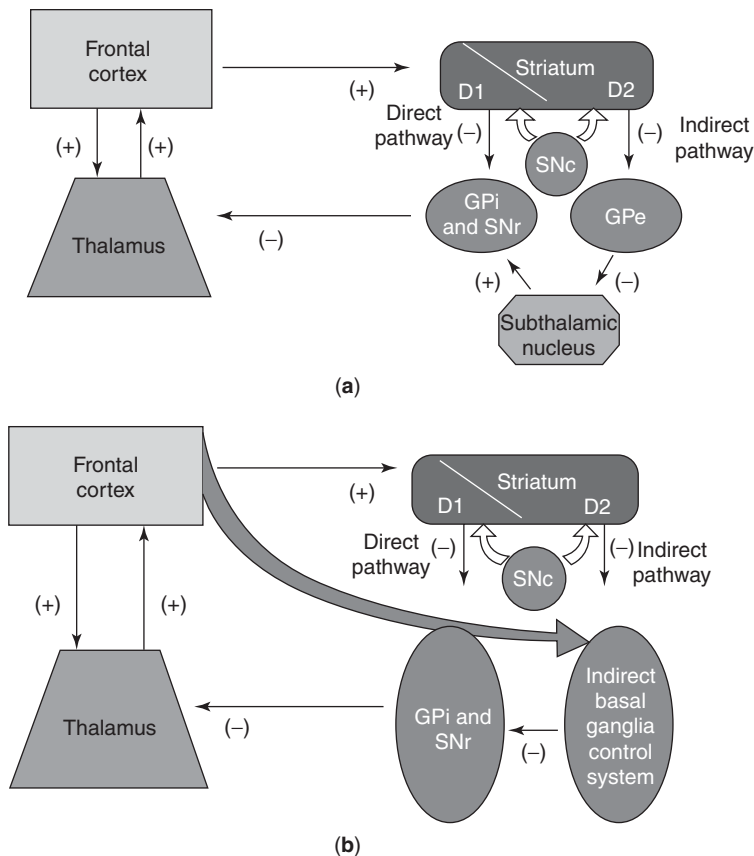

Figure 6.2 (a) Classic conception of direct and indirect frontal-basal ganglia-thalamocortical pathways. GPi and SNr, globus pallidus interna/substantia nigra, pars reticulata complex; GPe, globus pallidus externa. The frontal-subcortical circuit originates in the frontal cortex, which projects to striatum. The direct pathway projects from striatum to the GPi/SNr complex (the main output station of the basal ganglia), which projects to the thalamus, which has reciprocal, excitatory projections to and from the cortical site of origin. This pathway contains two excitatory and two inhibitory projections, making it a net positive-feedback loop. The indirect pathway also originates in the frontal cortex and projects to the striatum but then projects to the GPe, then to the subthalamic nucleus, then back to GPi/SNr, before returning to the thalamus and, finally, back to the frontal cortex. This indirect circuit has three inhibitory connections, making it a net negative-feedback loop. (b) Current conceptualization of prefrontal-basal ganglia-thalamocortical circuitry. Recent anatomic studies have called into question previous views of basal ganglia circuitry. Here, we refer to an indirect basal ganglia control system that consists of the GPe and the subthalamic nucleus. Connections within these structures are more complex than previously thought. The prefrontal cortex has excitatory projections to indirect pathway structures. In addition, the GPe directly projects to the GPi/SNr complex. Nevertheless, the net effect of activity in the indirect circuit still appears to be inhibition of the thalamus, thereby decreasing thalamocortical drive. The frontal-subcortical circuits originating in the lateral prefrontal cortex, orbitofrontal cortex, and anterior cingulate gyrus all pass through subcompartments of the medial dorsal nucleus of the thalamus. (From [18].)

6.2.1.2 Functional Imaging Studies. It is beyond the scope of this chapter to provide a thorough review of functional imaging studies in OCD. These studies have been particularly impressive in the degree of agreement across studies and methods and in their implications for treatment mechanisms. Functional methods have included both positron emission tomography (PET) and single photon emission computed tomography (SPECT) measuring cerebral blood flow (CBF) or metabolism and functional MRI (fMRI) measuring regional blood flow. Several functional studies have compared patients and controls in the resting state; others have scanned patients during symptom provocation or before and after treatment. While no finding is universally replicated, PET studies have generally shown elevated metabolism or regional cerebral blood flow (rCBF) in the OFC, anterior cingulate cortex, and basal ganglia [23]; these increases generally correlate with OCD symptoms.

Neuroimaging studies involving symptom provocation found strong correlations between OCD symptom expression and brain activation in the same regions found to be overactive, namely the OFC, anterior cingulate, and thalamus [24]. A recent SPECT study found greater responsivity of basal ganglia to symptom provocation in responders to sertraline [25]. Specifically, increases were seen in the OFC in the right caudate nucleus, left anterior cingulate (AC), and bilateral OFC. When the study was repeated with fMRI, again the right caudate, bilateral OFC, AC, and right caudate showed increased blood flow. Taken together, these studies link the expression of OCD symptoms with activation of the OFC, basal ganglia, thalamus, and limbic and paralimbic structures predominantly in the right hemisphere. In keeping with these findings, functional neuroimaging studies indicate that OCD patients show a different activation pattern [mesial temporal rather than striatal activation during learning of an implicit (procedural) sequence learning task], suggesting an alternate compensatory pathway for these subjects due presumably to striatal dysfunction. Further, these abnormalities appear specific to OCD [26].

Functional neuroimaging studies of OCD patients before and after treatment generally show decreases in the OFC or in the caudate nuclei in responders to treatment, since reductions in the caudate were seen both with fluoxetine and cognitive behavior therapy (CBT) [27]. Significant decreases were found in bilateral caudate glucose metabolism in responders to CBT compared with nonresponders [28]. These findings were not found in patients with depression, and so these appear to be disease-specific relationships. Another comprehensive examination of neural correlates of response to paroxetine in major depression, OCD, or concurrent OCD and depression also showed some diagnosis-specific differences. Treatment-related decreases in the OFC, thalamus, and ventrolateral prefrontal cortex (VLPFC) were noted for OCD responders; responders with major depression exhibited relative decreases in a large frontal area encompassing the VLPFC and medial, inferior, and dorsolateral frontal cortex. Thus, the drug-induced changes differed with respect to diagnosis and (not shown) paroxetine response versus nonresponse [29]. Perhaps most impressive has been the consistent finding that *elevated* OFC metabolism or blood flow predicts *greater* clinical response to treatment with a serotonin reuptake inhibitor (SRI). This finding has held across several functional imaging modalities and across several different SRIs.

Finally, abnormalities in the serotonin and dopamine transporter availability in unmediated OCD patients [30–33], as shown by SPECT, indicate both serotonergic and dopaminergic dysfunction in patients with OCD (although a PET study found

no difference in serotonin transporter availability in OCD [33]). These important findings are being explored with higher resolution studies. They are of particular interest because of the consistent evidence, reviewed below, that low doses of dopamine antagonists potentiate the effect of selective serotonin reuptake inhibitors (SSRIs), suggesting that overactivity of the dopamine system is part of the pathophysiology of OCD.

6.2.1.3 Magnetic Resonance Spectroscopy. Most magnetic resonance spectroscopy (MRS) studies of OCD have been conducted by Rosenberg and colleagues, who found significantly increased caudate glutamatergic concentration in pediatric OCD patients compared to healthy controls [34] and also found striking decreases in glutamate concentration in the caudate in 11 children with OCD after treatment with paroxetine [35]. These findings are consistent with PET studies of adult patients indicating increased blood flow and metabolism in treatment-naïve OCD patients. However, this drop in glutamate concentration appeared specific to SSRI treatment as it did not hold up for a group of OCD children responding to CBT [36]. It is notable that only caudate and not occipital glutamate concentration decreased, suggesting a localized effect of the drug. These studies, while intriguing, were done without sufficient resolution to distinguish glutamine and glutamate, and thus further understanding of these findings awaits replication with higher field strength machines.

Thus, taken together, and independent of imaging modality or type of treatment used, neuropharmacological hypotheses of OCD pathophysiology have supported the initial models put forward by Rapoport and Wise [37], Modell [12], Insel [37, 38], and Baxter [39] implicating cortical–striatal–thalamic–cortical (CSTC) loops. All of these models build on the discrete, parallel, neuroanatomic circuits connecting the prefrontal cortex, basal ganglia, and thalamus [40], although Saxena and colleagues [18] have summarized the more complex connections now documented within these structures and recent anatomic studies in primates. For example, there is a direct (excitatory) project from prefrontal cortex to the indirect (inhibitory) pathway structures. In light of the unique pattern of relationships between OCD and movement disorders, it is particularly interesting that the cortical–striatal connections provide a common substrate for both thoughts and planned movements. The excitatory projections in these circuits predominantly use glutamate as a neurotransmitter, while inhibitory ones mainly employ γ -aminobutyric acid (GABA). Several peptide transmitters also have roles within these pathways [41]. Other neurotransmitters (serotonin, dopamine, acetylcholine) modify the activity of projections between these structures. The net effect of the current model for OCD, in any case, is of an imbalance between direct and indirect pathways that leads to net overactivity of frontal–subcortical circuits.

6.2.1.4 Neuropharmacological Implications of Brain Imaging Studies in OCD. The imaging studies are almost all in agreement about the importance of the OFC, anterior cingulate, and ventral striatum. As mentioned, most consistent evidence relates OFC activity and treatment response. However, while the studies summarized above provide intriguing information about the pathways mediating OCD thoughts and behaviors, none has addressed the question of whether these findings are correlates of illness or trait markers. In fact, the normalization of caudate metabolism/blood flow with treatment and the normalization of caudate glutamate (Glx)

elevation with drug treatment support imaging results as being largely state rather than trait markers. These results, together with the absence of family studies, make these findings generally ambiguous with respect to the usefulness of imaging measures as intermediate phenotypes for genetic studies.

The major neuropharmacological implications of the model is that there is increased signaling from OFC to subcortical structures (i.e., ventromedial caudate and medial dorsal thalamus). This leaves numerous possible anatomic mediators for this effect, and the imaging data do not support any single pathway. There are strong data indicating that serotonergic systems modulate OCD symptoms, as reviewed in Section 6.3.

Inhibitors of the serotonin (5-HT) transporter [5-HT reuptake inhibitors (5-HT-RIs)] produce at least some clinical benefit in most patients with OCD. Dopamine systems are also suggested by the demonstration that dopamine-blocking agents may potentiate the response to SSRI drugs [42] and, as reviewed below, for some patients this mechanism seems to have particular importance. Other neurotransmitter systems have been implicated on the basis of either the circuitry described above or brain imaging studies and include glutamate, GABA, substance P, and cholinergic and (on the basis of symptom exacerbation by naloxone, an opiate antagonist) endogenous opioid mechanisms.

Perhaps the selective regional (caudate) change in glutamate in blood flow following SSRI treatment provides the most novel treatment-related information. Initial studies in adult OCD showed that the increased metabolic rates associated with OCD symptom severity decreased after SSRI treatment [27]. However, as the major excitatory neurotransmitter system in the circuitry subsuming OCD is glutamatergic and the majority of axon terminals in the caudate nucleus are glutamatergic, stimulating 5-HT, that is, via 5-HT_{2A} receptors, would be expected to decrease glutamatergic efferents from the prefrontal cortex to the caudate nucleus with resulting decreased caudate glutamate concentrations. To date, there have been no studies of glutamatergic agents as monotherapies for OCD that might address this model. Future imaging studies can further extend this model (e.g., through blood flow or metabolic studies of the effects of D₂-blocking augmenting agents).

As seen in Figure 6.1, three general circuits have been assumed based on clinical, imaging, and lesion studies [43]. The first is an orbitofrontal–dorsomedial thalamic loop by way of the internal capsule. This is likely to be glutamatergic [12]. The second involves the frontal cortex–ventral caudate, dorsomedial pallidum and the intralaminar, anterior and dorsomedial thalamic nuclei. While there are multiple neurotransmitters involved in these circuits, including substance P and GABA, there are also serotonergic projections to this component from the dorsal raphe to the ventral striatum. These projections are speculated to be inhibitory. Finally, the third component includes the limbic structures and accounts for the strong anxiety component of OCD; this circuit has strong projections from the anterior cingulate cortex.

Figure 6.2 is an update to our understanding of the circuitry of the basal ganglia–thalamic–frontal loops [18]. It is included because the close association between various movement disorders, basal ganglia lesions, and OCD provides one of the unique and important leads to understanding this illness. Since the original basal ganglia models were postulated, there have been some changes to how the model of basal ganglia circuitry is viewed, most prominently the direct connection between the frontal cortex and the internal pallidum (GPe).

While it is unlikely that one neurotransmitter system will explain the basis for this complex and heterogeneous disorder, efforts have centered largely on the role of the neurotransmitter serotonin. The serotonin hypothesis of OCD that this disorder is in some way due to 5-HT dysfunction, stems from drug treatment studies [44, 45]. As reviewed below, over two decades of work has documented the efficacy and relative (to placebo and to noradrenergic antidepressant drugs) specificity of the anti-OCD effect of 5-HT uptake inhibitors [46]. However, peripheral markers of 5-HT function have not consistently indicated an abnormality in untreated patients with OCD, and exacerbation of OCD by oral administration of the 5-HT agonist m-CPP has not been consistently found [47]. Some evidence for the serotonin hypothesis has been from the genetic studies reviewed below.

Perhaps the most direct relevance of imaging studies for neuropharmacology comes from the rather consistent data on regional change in MRS or functional imaging patterns with treatment. For example, a pattern found in pre- and posttreatment studies with pediatric OCD was consistent paroxetine-induced normalization in regional (i.e., reduction in caudate but not occipital) Glx levels that correlate with treatment response [34].

6.2.2 Genetic Studies

6.2.2.1 Overview. A systematic approach to understanding the genetics of OCD would include twin, family, segregation, linkage, and association studies. Twin studies indicate concordance for OCD symptoms ranging from 26 to 87% with widely varying phenotypic definitions and sample sizes [48]. Family studies support a genetic component for OCD, particularly for populations with early age at onset. The presence of tics in probands may also predict greater familiarity, as summarized by Grados et al. [49]. The findings appear complex, and heterogeneity by phenotype and by gender appears probable [50].

Genetic studies have been based on localization from linkage and from known pharmacological response. It is particularly encouraging that a 9p linkage site has recently been replicated [51, 52]. Because of the selective response of OCD to SRIs, the serotonin system has been the source for putative candidate genes. Cytogenetic studies, the studies of physical duplication, deletion, or disruption of chromosomes, are unexplored in OCD. One exception is the study of the 22q11 deletion, also known as velocardial facial syndrome (VCFS), a 3-MB microdeletion best recognized for its medical complications and association with psychosis [53]. However, OCD has also been associated with this same deletion in several studies, particularly for early-onset OCD [54, 55]. Segregation and linkage studies will not be reviewed here, but we will touch on candidate genes, which were targeted because they were involved in the metabolism of CNS neurotransmitters. Only studies with at least one independent replication are mentioned.

6.2.2.2 Serotonin. The serotonin transporter SLC6A4 on chromosome 17 is a target of SRIs. These drugs increase serotonin in the synapse by decreasing the transporter action. A functional gene 44-bp insertion/deletion polymorphism (*s* and *l* variants) within a gene promoter region (*5-HTTLPR*) has been identified and primarily *l* variants have been implicated [56], but there have been several non-replications. This gene is highly evolutionarily conserved and regulates the entire

serotonergic system. Both the serotonin transporter and some serotonin receptor subtypes such as 5-HT_{2A} and 5-HT_{2C} are highly expressed in the ventral striatum where they could influence the CSTC in OCD [57]. The gene has shown signals for multiple diagnoses, including ADHD, autism, bipolar disorder, and TD. The *ss* genotype is associated with poorer therapeutic response during treatment with antidepressant serotonin transporter (SERT) antagonists, the SSRIs. The 5-HT_{1D} *beta* receptor gene has variants of the coding region which have been studied with preferential transmission of variant G861C (C-to-G) substitution preferentially transmitted to affecteds [58, 59] with other partial replications [60].

6.2.2.3 Dopamine. Both animal and human imaging studies have underlined the involvement of the dopaminergic system in repetitive behaviors [61, 62]. The association with movement disorders and basal ganglia disease and the well-documented efficacy of the D₂-blocking agent haloperidol as an augmenting agent all implicate the dopamine system in OCD. For a recent review, see [63]. There is evidence that the dopamine transporter density in the basal ganglia differs in unmedicated OCD patients in comparison to normal controls [30], suggesting further that the dopaminergic neurotransmitter system is involved in the pathophysiology of OCD. The *DRD4* gene codes for a receptor with several functional polymorphisms in the form of variable numbers of tandem repeats (VNTR) identified within a particular intracellular peptide segment. The 7 repeat has been linked to ADHD, but several studies have found this association with OCD (although the specific allelic associations have been inconsistent [64–67]).

6.2.2.4 Glutamate. Several lines of evidence suggest that OCD could be a consequence of glutamatergic dysfunction. Brain imaging profiles (reviewed above) using a variety of neuroimaging techniques demonstrate alterations in the OFC, basal ganglia, and thalamus which normalize with treatment [68, 69]. These regions are linked in circuits within which glutamate is the primary excitatory neurotransmitter [70–72]. Moreover, a transgenic mouse model (see below) suggests aggravation of TD/OCD-like behavior with glutamatergic drugs [73]. Positive associations have been reported for NMDA receptors (*GRIN2B*) [72] and for *GRIK2* (a kainate receptor) recently also associated with autism [71].

6.2.2.5 Neurotransmitter Metabolism. The X chromosome *MAOA* gene encodes monoamine oxidase A which is found in serotonergic and catecholaminergic brain neurons. (There are, however, no controlled studies indicating efficacy of MAO inhibitor drugs in OCD.) A polymorphism *MAOA* Eco/Rv was found to be significantly more frequent in OCD females in two studies [74, 75]. The enzyme catechol-*O*-methyl transferase (COMT) is the major degradation enzyme for catecholamine neurotransmitters. A Val–Met substitution polymorphism in codon 158 results in low enzymatic activity [76]. COMT's location in the 22q11 region associates it with VCFS, and, as mentioned above, children with VCFS frequently manifest anxiety and OCD [54].

6.2.2.6 Developmental Genes. There have been isolated reports of genes related to neurodevelopment. *Hoxb8*, a member of the mammalian homeobox-containing group of transcription factors, is of interest as disruption shows excessive grooming

in mice [77, 78]. The developmental gene brain-derived neurotrophic factor (BDNF) was found to show significant association with OCD [79]. This is an interesting, if nonspecific, finding which bears replication.

Although genetic studies of OCD have been productive in yielding several replicated significant associations, none yet leads to new insight with respect to the neuropharmacology of OCD. One exception may be the finding of association with the mu opioid receptor [80] (see discussion of new clinical agents in Section 6.3).

6.2.3 Animal Models of OCD

Animal models are of interest in OCD for several reasons. Many OCD habits such as grooming, checking, and avoidance of fecal contamination have led to ethological models for this disorder. This implies the notion of highly conserved neural circuitry for such behavior. Unfortunately, efforts to elucidate the neural circuitry subserving OCD have been hampered by the lack of good animal models and, while some appealing “semiclinical” models (such as canine acral lick) have been published [81], other models have provided contradictory evidence [82–84]. Unlike movement disorders, many of the behaviors that are seen in OCD are inherently unique to humans (e.g., the belief that the thoughts or behaviors are senseless).

One proposed model is schedule-induced polydipsia (SIP). Food-deprived rats drink excessively when exposed to an intermittent feeding schedule, and SIP may be a displacement behavior in response to stress [85]. SSRIs reduce SIP and displacement behaviors after 14–21 days of treatment, suggesting a parallel with treatment of OCD in humans [86]. This parallel may be deceiving, however, as other antianxiety agents may increase SIP [87]. Some animal models are intriguing, such as the quinpirole (an agonist of D₂-like dopamine receptors) rat model in which repetitive cleaning behaviors are partially ameliorated by clomipramine [84]; this model focuses interest on the role of dopamine in the disorder [88]. In spite of appealing face validity (e.g., [89]), a variety of neurotransmitter systems are implicated [90]. A transgenic mouse model of comorbid TD and OCD was created by expressing a neuropotentiating cholera toxin transgene in a subset of dopamine D₁ receptors expressing neurons thought to induce cortical and amygdala glutamate output [91, 92]. It is anticipated that future models using the serotonin transporter and other putative genes will be fruitful.

To date, however, the best animal models have been inspired by the known brain circuitry of OCD. A series of studies from France has addressed regional control within the basal ganglia in primates that mediate some stereotypic and ticlike movements which might be seen as relevant to TD or possibly OCD [93, 94]. These studies utilized microinjections of bicuculline, a GABA antagonist, into various territories of the external globus pallidus (GPe). The regions were selected based on the known striato-pallidal projections to sensorimotor, associative, and limbic regions. The authors hypothesized that while sensorimotor territory injections would induce reversible abnormal movements, injections into the associative and limbic territories of the GPe would produce behavioral disorders. In fact, the bicuculline microinjections induced stereotypy when performed in the limbic part of the GPe (and ADHD-type behaviors when performed in the associative part); this is of particular interest when taken together with the modified view of the prefrontal–basal ganglia circuitry (see Fig. 6.2b) in which direct frontal GPe connectivity is now included in the model.

6.3 CLINICAL PSYCHOPHARMACOLOGY

This section focuses on selective studies addressing the major neuropharmacological issues in OCD, but excellent more general treatment reviews are available [95].

6.3.1 Effective Monotherapies: Controlled Trials

The past two decades have seen highly consistent findings that drugs that inhibit reuptake of serotonin either nonselectively (clomipramine) or selectively provide significant benefit for OCD. The major controlled trials are summarized in Table 6.1. Where pediatric trials have also been carried out, these are included. The selective effect of the SSRIs is particularly important here, as one or two double-blind comparisons with selective noradrenergic uptake inhibitors (e.g., desipramine [96]) show no efficacy of the noradrenergic medication. The well-documented efficacy of SSRIs for OCD has transformed the treatment of the disorder which earlier was treated predominantly with psychotherapy. It further differentiates OCD from depression and other anxiety disorders which may respond well to other agents predominantly affecting NE metabolism.

Table 6.1 contains representative high-quality studies documenting the efficacy for the serotonin uptake inhibitors in OCD. While clomipramine had a slightly more troublesome side-effect profile (including dry mouth, constipation, and some EKG changes), there is some consensus that it is more effective than the more selective serotonin uptake inhibiting agents. It is beyond the scope of this chapter to review the adverse effects of each of the drugs presented here. While the SSRIs are the best tolerated medications for OCD, some subjects, particularly children, have significant side effects, such as agitation, nausea, and in a small percent of cases an increased risk of suicidal ideation [115, 116]. However, generally the effect size for SRIs in OCD is substantial, and the suicidal thoughts occur early in treatment and can be handled with careful monitoring during this period.

It is also beyond the scope of this chapter to review behavioral treatment of OCD, but the reader should be aware that many find cognitive behavior therapy to be as important or more so than drug treatment for this condition [117, 118].

6.3.2 Augmenting Agents

Because the majority of patients classified as “responders” have only partial response to monotherapy with serotonin drugs, it is significant that a small but important group of controlled trials has shown benefit from the addition of another agent. These are considered augmenting agents as their effect appears to be only in conjunction with a SRI. Benefit has been shown most consistently for typical and atypical antipsychotic agents. Pharmacological augmentation strategies for treatment-resistant OCD are also well covered in a recent review [119]. Table 6.2 shows controlled trials for augmenting agents in OCD.

Table 6.2 contains a selective list of high-quality placebo-controlled studies that document the efficacy of typical and atypical antipsychotics as augmenting agents added to selective or nonselective SRIs. A single, as yet unpublished controlled trial also documented the efficacy of clonazepam as an augmenting agent [128], but the typical and atypical antipsychotics remain the only group of medications for which

TABLE 6.1 Serotonin Uptake Inhibitor Efficacy in OCD

Study	N	Design and Dose	Results	Comments
Clomipramine				
Adults: Katz et al., 1990 [97]	263	10 wks; 100–300 mg/d	> 50% of CMI group (vs. <5% for placebo) became subclinical, based on NIMH-OC ($p < 0.001$)	Efficacy shown in acute trial and maintained in a 1-yr DB extension
Children: DeVaugh-Geiss et al., 1992 [98]	60	8 wks; max. daily dose: 3 mg/kg or 200 mg, whichever less	Mean CY-BOCS reduction: 37% (vs. 8% for placebo) ($p < 0.05$)	Side effects typical of tricyclic antidepressants; efficacy maintained in 1-yr OL extension
Fluoxetine				
Adults: Montgomery et al., 1993 [99]	214	8 wks; fixed dose: 20, 40, 60 mg/d	40 and 60 mg were superior; response rates (Y-BOCS and CGI): 40 mg: 48%; 60 mg: 47% (vs. placebo: 26%, 20 mg: 36%) ($p < 0.05$)	16-wk controlled extension offered for responders; response maintained; nonresponders improved in OL extension on 60 mg
Adults: Tollefson et al., 1994 [100]; Tollefson et al., 1994 [101]	355	13 wks; fixed dose: 20, 40, 60 mg/d	All doses superior to placebo; response rates (Y-BOCS): 32–35% for all doses (vs. 8% for placebo) ($p < 0.001$)	13 wks was minimum to see effects of 20 mg; in OL extension, responders maintained acute trial gains and 60 mg yielded added benefit; late-emergent adverse events: asthenia (11%), rhinitis (10%), flu syndrome (10%), abnormal dreams (9%)
Children: Geller et al., 2001 [102]	103	13 wks; max. dose: 60 mg/d	Response rates (CY-BOCS): 49% (vs. 25% for placebo) ($p = 0.03$)	20–60 mg/d effective and well tolerated; side effects and drop-out rates similar for drug and placebo
Fluvoxamine				
Adults: Goodman et al., 1997 [103]	320	10 wks; max. dose: 300 mg/d	Response rates (CGI): 43% (vs. 11% for placebo) (p not provided)	Of all on fluvoxamine, mean Y-BOCS at wk 10 still in moderate range; of responders, mean decreased to mild range
Adults: Hollander et al., 2003 [104]	253	12 wks; 100–300 mg/d of CR fluvoxamine	Response rates (CGI-I): 44% (vs. 23% for placebo) ($p = 0.002$)	Excluded from study if history of nonresponse to SRIs; response seen at wk 2; CR allows for more aggressive dosing

Children: Riddle et al., 2001 [105]	120	10 wks; 50–200 mg/d	Based on CY-BOCS, significant differences seen as early as wk 1 ($p = 0.007$); response rates (CY-BOCS): 42% (vs. 26% for placebo) ($p = 0.06$)	Rapid onset of action
Sertraline				
Adults: Greist et al., 1995 [106]; Greist et al., 1995 [107]	324	12 wks; fixed dose: 50, 100, 200 mg/d	Pooled sertraline group better than placebo, based on Y-BOCS ($p = 0.006$) and CGI-I ($p = 0.01$); response rates (CGI-I): 39% (vs. 30% for placebo)	Larger placebo effect than usual; those completing 3 mos of sertraline continued to improve during 40-wk extension
Adults: Koran et al., 2002 [108]	223	649 pts in 16-wk, flexible dose, SB trial; responders got additional 36 wks SB; 223 responders at 52 wks got 28 wks of 50–200 mg/d DB	During DB, sertraline better than placebo on 2 of 3 primary outcomes: dropout due to relapse/poor response (9% vs. 24%) ($p = 0.006$) and acute exacerbation of symptoms (12% vs. 35%) ($p = 0.001$)	Long-term treatment generally well tolerated; efficacy sustained among prior responders
Children: March et al., 1998 [109]	187	12 wks; up to 200 mg/d at 4 wks, then maintained for 8 more wks	Response rates (CGI-I): 42% (vs. 26% for placebo) ($p = 0.02$)	Short-term safety and effectiveness shown; efficacy differences seen at wk 3 and persisted
Paroxetine				
Adults: Hollander et al., 2003 [110]	348	12 wks; fixed dose: 20, 40, 60 mg/d	40 and 60 mg/d effective ($p < 0.05$); mean CY-BOCS reduction: 40 mg: 25%, 60 mg: 29% (vs. placebo: 13%, 20 mg: 16%)	Long-term effectiveness shown (263 acute trial responders enrolled in 6-mo, flexible dose, OL trial; 105 responders to that OL trial randomized to 6 mo, fixed dose, DB trial); some mild discontinuation symptoms if abruptly stop

(continued)

TABLE 6.1 (Continued)

Study	N	Design and Dose	Results	Comments
Adults: Kamijima et al., 2004 [111]	191	12 wks; 20–50 mg/d	Response rates (Y-BOCS): 50% (vs. 24% for placebo) ($p = 0.0003$)	Effective and generally well tolerated; those not adequately responding to suggested dose of 40 mg/d may benefit from 50 mg/d
Adults: Zohar & Judge, 1996 [112]	406	12 wks; paroxetine: 20–60 mg/d; CMI: 50–250 mg/d	Response rates (Y-BOCS): 55% for paroxetine ($p = 0.001$) and 55% for CMI ($p = 0.005$) (vs. 35% for placebo)	Paroxetine more effective than placebo and comparable to CMI; paroxetine better tolerated than CMI, based on some measures; more anticholinergic adverse events for CMI (53%) than paroxetine (28%), 12% for placebo
Children: Geller et al., 2004 [113]	207	10 wks; 10–50 mg/d	Response rates (CY-BOCS): 65% (vs. 41% for placebo) ($p = 0.002$)	Effective and generally well tolerated; especially gradual titration and tapering suggested due to nonlinear pharmacokinetics
Citalopram				
Adults: Montgomery et al., 2001 [114]	401	12 wks; fixed dose: 20, 40, 60 mg/d	Response rates (Y-BOCS): 20 mg: 57%, 40 mg: 52%, 60 mg: 65% (vs. 37% for placebo) ($p < 0.05$)	All three doses more effective than placebo; need larger sample to see effects of different doses; suggest starting at 20 mg, although 60 mg may be useful if need rapid response

Note: Unless noted, studies are multicenter, randomized, double-blind, placebo-controlled, acute trials with parallel design. Information on extension trials, if conducted, is provided under Comments. CGI: Clinical Global Impressions; CGI-I: Clinical Global Impressions-Improvement scores; CMI: clomipramine; DB: double blind; SB: single blind; NIMH-OC: National Institute of Mental Health Global Obsessive-Compulsive Rating Scale; OL: open label; Y-BOCS: Yale-Brown Obsessive-Compulsive Scale; CY-BOCS: Children's Yale-Brown Obsessive-Compulsive Scale; CR: controlled release.

TABLE 6.2 Controlled Trials of Augmenting Agents in Adults with OCD: Typical and Atypical Antipsychotics

Study	N	Design and Dose	Results	Comments
Haloperidol				
McDougle et al., 1994 [120]	34	OCD pts (with or without a secondary chronic tic d/o) refractory to 8 wks of fluvoxamine (max of 300 mg/d given for over 7 wks) given 4 wks haloperidol or placebo addition; haloperidol dose: 2 mg/d for 3 days, increased by 2 mg every 3 days, to a max of 10 mg/d	Based on Y-BOCS and CGI, 11/17 (65%) responded (vs. 0/17 for placebo) ($p < 0.0002$); of those with comorbid chronic tics, 8/8 responded [vs. 3 (33%) of 9 without tics or family history of tics] ($p = 0.007$)	Support for role of dopamine dysregulation in some OCD patients, particularly those with tic disorder; little or no benefit if no tic disorder; risk of tardive dyskinesia
Risperidone				
McDougle et al., 2000 [42]	36	Patients with primary OCD treated for 6 wks with risperidone ($N = 20$) or placebo ($N = 16$) addition to their SRI; risperidone started at 1 mg/d for 1 wk, with dosage increased 1 mg every week until max of 6 mg/d, as tolerated	Of study completers and based on CGI, 9/18 (50%) responded (vs. 0/15 for placebo) ($p < 0.005$)	Patients with or without comorbid tic disorder or schizotypal personality disorder may benefit; mild transient sedation; risk of tardive dyskinesia
Hollander et al., 2003 [121]	16	Patients treated for 8 wks with risperidone or placebo addition; risperidone initiated at 0.5 mg/d and gradually increased by 0.5 mg/d every 7 days over first 6 wks until max of 3 mg/d or experienced therapeutic effects or side effects	Based on Y-BOCS and CGI, 4/10 (40%) responded (vs. 0/6 for placebo) ($p = 0.12$)	Small sample but consistent with literature indicating 30–50% benefit from atypical antipsychotic addition

(continued)

TABLE 6.2 (Continued)

Study	N	Design and Dose	Results	Comments
Erzegovesi et al., 2005 [122]	39	After 12 wks of OL fluvoxamine monotherapy (max of 300 mg/d; initial study $N = 45$), both responders and nonresponders (total $N = 39$) randomly assigned to 6-wk DB addition of low-dose (0.5 mg) risperidone or placebo; fluvoxamine dose maintained	Significant interaction of “add-on treatment” \times “response” \times “time” ($p = 0.001$); based on Y-BOCS and CGI, during DB phase, 5 (50%) on risperidone and 2 (20%) on placebo became responders	Low dose effective; add-on treatment effective <i>only</i> in fluvoxamine-resistant subgroup; fluvoxamine-responder group had poorer effect of addition than did placebo group
Olanzapine				
Bystritsky et al., 2004 [123]	26	Treatment-refractory patients without significant comorbidity treated for 6 wks with olanzapine (started at 2.5 mg, increased to 5 mg/d for days 4–7, then 5–20 mg/day) or placebo, while continuing their SRI at stable dose	Based on Y-BOCS, 6/13 (46%) responded (vs. 0/13 for placebo) ($p = 0.01$), with mean Y-BOCS decreasing 16% in olanzapine addition group	Effect on OCD symptoms appears not to be due to antipsychotic or mood-stabilizing effects; no extrapyramidal side effects; of olanzapine patients, two (15%) discontinued: one due to lack of effect and sedation, one due to weight gain
Shapira et al., 2004 [124]	44	Partial or nonresponders to 8-wk OL fluoxetine trial (40 mg in almost all pts) treated with 6 wks olanzapine (5–10 mg) or placebo addition to fluoxetine	Groups similar; based on Y-BOCS, both groups improved over time	May have needed longer prior monotherapy

Quetiapine

Denys et al., 2004 [125]	40	Patients without significant comorbidity treated for 8 wks of up to 300 mg/d quetiapine or placebo, in addition to their SRI; quetiapine initiated at dose of 50 mg/d and increased at fixed schedule (wks 1–2: 100 mg/d; wks 3–6: 200 mg/d; wks 7–8: 300 mg/d)	Based on Y-BOCS and CGI, 8/20 (40%) responded [vs. 2/20 (10%) for placebo] ($p = 0.03$)	Effective, especially for severe obsessions; response seen within 4–6 wks; most common side effects: somnolence, dry mouth, weight gain, dizziness
--------------------------	----	---	---	--

Buspirone (Anxiolytic)

Grady et al., 1993 [126]	14	Crossover design, 4 wks each, placebo and buspirone addition to ongoing fluoxetine; buspirone dosage increased over 2 wks; all had stable dose of 60 mg/d for final 2 wks of active treatment	No significant effect of drug; only one patient had clinically meaningful response to buspirone (vs. 0 for placebo)	Parallels earlier study by same group showing lack of improvement for buspirone added to CMI; one patient withdrew after a seizure
McDougle et al., 1993 [127]	33	OCD patients refractory to 8 wks of fluvoxamine (up to 300 mg/d) given 6 wks buspirone ($N = 19$; initially 15 mg/d in 3 divided doses, then increased by 15 mg every other day to a max of 60 mg/d in 3 divided doses) or placebo ($N = 14$) addition to fluvoxamine continued at the same dose	No differences: based on Y-BOCS and CGI, 2/19 (11%) responded [vs. 2/14 (14%) for placebo]	Negative study

(continued)

TABLE 6.2 (Continued)

Study	N	Design and Dose	Results	Comments
Clonazepam (Anxiolytic)				
Pigott et al., 1992 [128]	18	2–6 mg/d added to ongoing CMI or fluoxetine (other information not available)	Added benefit demonstrated on 1 of 3 OCD rating scales	Benzodiazepine with preferential effects on serotonergic system; especially helpful if anxiety prominent; improvement seen in hours to days; typically started at 0.5 mg once or twice daily, with max of 5 mg/d when used as an antiobsessional
Desipramine (TCA)				
Barr et al., 1997 [129]	33	Desipramine or placebo added for 6 or 10 wks to SSRI treatment; desipramine daily dose adjusted weekly to obtain plasma level > 125 ng/mL if tolerated; mean final plasma level was 148.3 ng/mL (SD = 82.0)	Based on Y-BOCS, there was no drug-by-time interaction at wk 6 ($p = 0.07$) or wk 10 ($p = 0.45$)	Desipramine's relatively specific inhibition of norepinephrine reuptake was not an effective addition [30 patients completed 6 wks; 25 of these enrolled in extension; 23 (10 on desipramine, 13 on placebo) completed 10 wks]
Nortriptyline (TCA)				
Noorbala et al., 1998 [130]	30	DB nortriptyline (50 mg/d) or placebo added to 150 mg/d CMI for 8 wks	Based on Y-BOCS, both improved; but active addition showed advantage by wk 4 ($p = 0.007$); by wk 8, $p < 0.0001$	Rapid onset of action; (sample mostly female)

Lithium

McDougle et al., 1991 [131]	30	Two trials: 2-wk ($N=20$) and 4-wk ($N=10$) augmentation of ongoing fluvoxamine (200–300 mg/d); lithium initially given at 900 mg/d in 3 divided doses; dosages then adjusted to keep serum levels between 0.5 and 1.2 mmol/L	Significant change in Y-BOCS and CGI in trial 1 ($p<0.05$) but not in trial 2; based on Y-BOCS and CGI, 2/11 (18%) and 0/5 of patients having 2 wks or 4 wks, respectively, of lithium addition were responders (vs. 0/9 and 0/5 for placebo)	Generally not effective; some OL treatment also given subsequently; even 4 wks was not effective for most
-----------------------------	----	---	---	---

Pindolol

Dannon et al., 2000 [132]	16	6 wks of pindolol ($N=8$; 2.5 mg t.i.d.) vs. placebo ($N=6$) addition to paroxetine (up to 60 mg/d)	Based on Y-BOCS, pindolol was superior to placebo ($p<0.01$) after wk 4	Results based on $N=14$ as two placebo patients dropped out
---------------------------	----	---	---	---

Inositol

Fux et al., 1999 [133]	10	Crossover design with 18 g/d inositol or placebo for 6 wks each, in addition to ongoing SRI (dosage range was 40–60 mg/d for fluoxetine; 200–250 mg/d for fluvoxamine; 150–225 mg/d for CMI)	Both groups improved ($p<0.000$); no significant group differences	No added effects from inositol (putative site of action intracellular; SRIs synaptic)
------------------------	----	--	--	---

Note: Unless noted, studies are double blind and placebo controlled with SRI-refractory OCD patients. CGI: Clinical Global Impressions; DB: double blind; OL: open label; SRI: serotonin reuptake inhibitor; SSRI: selective serotonin reuptake inhibitor; TCA: tricyclic antidepressant; Y-BOCS: Yale-Brown Obsessive-Compulsive Scale.

there are really well-documented augmenting effects for the treatment of OCD. Increased clarity regarding criteria for defining treatment resistance and nonresponse would be useful in studies of augmenting agents and treatment in general [134].

6.3.3 Miscellaneous Pharmacological Trials of Interest

Tables 6.1 and 6.2 do not include unblinded trials or double-blind comparisons of active agents that do not also include a placebo. However, there is an intriguing list of agents for which either convincing case series or small controlled trials suggest other pharmacotherapies. Some small open studies indicate that tramadol (a mu opioid agonist) may be efficacious for OCD [135, 136]. Also, anecdotal evidence and a recent small short-term placebo-controlled, double-blind study [137, 138] suggest that oral morphine sulfate may be of benefit in treatment-resistant OCD, although, among other questions, it is unclear how often the drug should be administered. While clonazepam is widely used as an anxiolytic in OCD, a recent double-blind placebo-controlled study showed no evidence for its usefulness as monotherapy [139]. One early study examined clonazepam as an augmenting agent (see Table 6.2); an early crossover study provided initial support for its usefulness as monotherapy [140]). Other studies suggest that venlafaxine, a serotonin–norepinephrine reuptake inhibitor might be effective as monotherapy or augmenting agent [119, 141, 142]; see [143] for a review. A small study of nicotine patches given to nonsmoking OCD patients found significant improvement compared to placebo [144]; this most probably reflects a nonspecific anxiolytic effect of nicotine. Lastly, in light of evidence of hyperactivity of glutamatergic circuits in OCD, an interesting new direction involves riluzole, an antiglutamatergic agent that currently is under open-label study in adults (also, for a related published case report, see [145]).

6.3.4 Induction of Obsessive-Compulsive Symptoms

Evidence is particularly impressive that antipsychotics may augment SRI treatment of OCD. In contrast to this effect is the growing number of case reports documenting the provocation or worsening of OCD with both typical and atypical antipsychotics [146]. There has been some impression that this effect is more salient with clozapine. Speculatively, the 5-HT₂ antagonist effect of the atypical antipsychotics may disinhibit dopamine neurons, producing increased output from the orbitofrontal/cingulate cortex and thus precipitating or exacerbating OCD based on the model circuitry shown above [147]. It also has been speculated that the D₂ and 5-HT₂ receptor occupancy of atypical antipsychotics at low doses may actually antagonize the SSRI effects. Management suggestions have therefore included a trial of increased dose of the atypical agent before discontinuation [148]. Following an analysis of the effects of the nonselective 5-HT receptor agonist mCPP, which worsened OCD symptoms, a small double-blind study found that sumatriptan, a 5-HT_{1D} receptor agonist, also worsened OCD symptoms [149]. Finally, a preliminary study indicated that the mu opioid antagonist naloxone exacerbates OCD symptoms [150], although, paradoxically, another mu opioid antagonist, naltrexone, showed some efficacy in treating compulsive self-injurious behavior [151].

6.3.5 Immunomodulatory Treatments

Based on the observation that some childhood-onset OCD patients had onset apparently in relationship to infection with group A β -hemolytic streptococcus (GABHS), a subgroup of children were proposed who were hypothesized to have an autoimmune-based form of the disorder. As a partial test of this model, two treatments were examined. In the first, a controlled treatment trial of intravenous immunoglobulin (IVIG; 1 g/kg/day on two consecutive days) was carried out. The second was an open trial of plasmapheresis consisting of four to five single volume exchanges over a two-week period. These extremely interesting findings have not yet been replicated. A single trial of penicillin prophylaxis was negative [152]. In spite of growing evidence linking GABHS infection and onset of OCD [153], there remains only a single controlled trial documenting the efficacy of immunomodulatory treatment [154, 155].

6.4 EXPERIMENTAL NONPHARMACOLOGICAL TREATMENTS

In spite of the major advances in drug treatment of OCD over the past two decades, at least 10% of the OCD population remains severely affected. This amounts to hundreds of thousands of patients with a debilitating disease without effective treatment. Recent developments in techniques for direct brain manipulation have been applied both to neurological and psychiatric disorders. Given the close connection between OCD and a variety of movement disorders, it is of great interest that selected neurosurgical lesions such as subcaudate tractotomy and deep brain stimulation (DBS) have been effective in the treatment of Parkinson's and other movement disorders. Selective reviews are given below with special focus on the implications for the circuitry and potential neuropharmacology of OCD.

6.4.1 Neurosurgery

The data on neurosurgical lesion treatment for OCD consist of open trials of small numbers of patients with intractable OCD and typically high rates of comorbid Axis I disorders. Response rates across centers vary from about 20 to 60% with varying diagnostic methods and surgical procedures across centers. No randomized double-blind trials have been reported [156]. Various lesions interrupting the CSTC loops have included: anterior capsulotomy, subcaudate tractotomy, limbic leucotomy, and anterior cingulotomy. These are summarized in Table 6.3 and, as seen, interrupt the major pathways in circuits shown in Figure 6.1.

The focus of neurosurgical lesions for OCD is principally to interrupt frontal–basal ganglia and frontal–limbic connections. Reports of success in OCD patients have followed open trials of anterior capsulotomy, a lesion that aims to target connections between dorsomedial thalamus and orbital and medial prefrontal cortex. The newer technique of gamma knife capsulotomy has, at least in theory, enabled controlled trials because of the noninvasive nature of a sham lesion. (The sites of neurosurgical lesions are also the focus for trials of DBS, which, similarly, lends itself more easily to controlled trials.) It is beyond the scope of this chapter to review these studies in greater detail in the absence of any controlled trials documenting efficacy.

However, it is important to note that the circuitry involved is the same as that implicated by brain imaging studies (see above).

6.4.2 Transcranial Magnetic Stimulation

Transcranial magnetic stimulation [TMS, or repetitive transcranial magnetic stimulation (rTMS)] has been proposed as therapeutic for various psychiatric disorders, mainly depression, although stimulation characteristics remain in dispute [158]. In OCD, TMS studies have been used to explore abnormal responsivity of brain circuits, with preliminary findings of decreased neuronal inhibition and a reduced cortical silent period in the primary motor area for TD and OCD [159, 160]. While preliminary, these studies provide suggestive complementary evidence of abnormalities in cortical motor circuitry. However, to date, TMS does not appear to be therapeutically useful in OCD, although this view is based on small sample studies [161, 162] and only a single controlled trial [161].

6.4.3 Deep Brain Stimulation

The realization that chronic high-frequency stimulation resulted in clinical benefits analogous to those of neurosurgical lesioning transformed the use of functional neurosurgery for the treatment of movement disorders (primarily tremor and Parkinson's disease). The use of the more flexible and reversible DBS techniques, instead of irreversible surgical ablations and tract lesions, has been expanded to the treatment of chronic pain and psychiatric disorders, particularly intractable depression and OCD [163]. The site of stimulation overlaps somewhat with the sites of surgical lesions described in Table 6.3 and Figures 6.1 and 6.2, although there is an impressive case report of ventral caudate stimulation [164]. Thalamic and basal ganglia stimulation are most frequently used for movement disorders [165]. DBS has largely replaced pallidotomy in the treatment of Parkinson's disease.

The clinical applications have preceded the scientific understanding of the mechanisms of action of DBS, and it has been puzzling how stimulation initially thought to activate neurons could have therapeutic outcomes similar to those from lesioning of target structures. Basic work is still going on to address such fundamental topics as the volume of tissue influenced by DBS, the effects on neurotransmitter systems, and functional imaging of DBS, but several alternate hypotheses on the physiological changes induced by stimulation remain. From a neuropharmacological standpoint, it would appear that DBS affects glutamate, dopamine, and GABA systems [165]. To date, only a small number of studies have been published on DBS for OCD. Nuttin et al. [166] reported on the effects of stimulation of the internal capsule of four patients with OCD at a site described as identical to that used in capsulotomy. Beneficial effects were described in three of the four patients. The same group reported on long-term follow-up in six patients [167]. This latter study was of special interest as it included double-blind evaluation with and without the stimulation on. Three of the six were considered responders to chronic stimulation. There also has been a report of a single case with dramatic improvement [168]. Most recent is a study [169] of four cases with a short-term, blinded, off-on design and long-term, open follow-up; one patient improved dramatically during blinded and open treatment and a second showed moderate benefit during open follow-up. DBS

TABLE 6.3 Summary of Procedures for Modern Neurosurgery for Psychiatric Disorders

Procedure	Target	Rationale	Current Indications
Anterior cingulotomy	Anterior cingulum	Disconnect Papez circuit	Affective disorders, OCD, anxiety disorders
Subcaudate tractotomy	Frontobasal white matter	Disconnect frontolimbic connections	Affective disorders, OCD, anxiety disorders
Limbic leukotomy	Anterior cingulum and frontobasal white matter	Cingulotomy + subcaudate tractotomy	OCD, affective disorders
Capsulotomy	Anterior limb of internal capsule	Disconnect frontolimbic and caudate-putaminal connections	OCD, anxiety disorders, panic disorder

Source: From [157].

continues to be of interest as a probe of putative circuitry, as reports of improvement of obsessive-compulsive symptoms in patients with Parkinson's disorder, for example, suggest that subthalamic nucleus stimulation may also prove helpful [170]. For the moment, however, most work involves the placement of probes in the same area where subcaudate tractotomy is carried out, with some electrodes in part of the ventral striatum. It is clear that this is a very early stage of treatment development, but these small careful trials will be of importance in elucidating the circuitry of OCD with possible discovery of numerous possible etiologic sites for the disorder within the same circuitry.

6.5 SUMMARY

The advances of the last two decades have revolutionized our understanding and treatment of OCD. The disorder is now readily diagnosed by health care professionals, and appropriate treatments—drug treatment and behavior therapy—are available. Remarkably, the brain imaging studies have served to differentiate OCD from other anxiety disorders, and there is surprising agreement on the functional and some aspects of the anatomic abnormalities. Less successful have been the candidate gene studies, although the agreement of two independent linkage studies on a 9p locus is important. Also surprising is the degree to which there is some agreement on the gene for the D₄ receptor and 5-HT transporter in OCD. Efforts to subgroup the phenotype in terms of symptom profile have not been particularly successful, and considerably more work needs to be done, perhaps using other more neurobiological measures as alternate endophenotypes. Before this can be done, however, the conflicting data about whether brain imaging results reflect state or trait markers need to be resolved. To this end, twin and family imaging studies are needed for these and other biological measures. Such studies are ongoing at several sites.

7.1 INTRODUCTION

Schizophrenia is a chronic psychotic illness with an unknown pathophysiology and etiology. It is the prototypical psychotic illness because of its pervasive and chronic manifestations and its human impact. Because the symptoms have their onset in early adult years and frequently run unabated throughout life, its medical need is high. Treatments are palliative, and partially effective.

The causes and mechanisms of illness will undoubtedly be complex. Neither a single brain region nor a single neurochemical alteration seems likely but several. Brain systems are thought to underlie the symptoms of the illness; some evidence suggests that the limbic system is the substrate for psychotic symptoms, the prefrontal neocortex for cognitive symptoms, and the frontoparietal cortex for the affective symptoms. A genetic vulnerability with environmental determinants of etiology is the theoretical construct guiding research.

Research into the biological basis of schizophrenia has become more informative as the tools and understanding in neuroscience itself have become more sophisticated. It has only been recent that tools for human brain research have been sensitive and reliable enough to contribute. But now, human brain imaging techniques, postmortem tissue analysis, and genetic tools are the main sources of data informing schizophrenia biology. Animal models for aspects of the illness are based on growing knowledge about the brain in schizophrenia and its genetic underpinnings. Advances in the understanding of the biology of schizophrenia are necessary to support new drug development and modify the course of illness.

7.2 CLINICAL PHENOMENOLOGY AND TREATMENT

Schizophrenia is characterized by a constellation of symptoms that include psychosis, cognitive deficits, and negative symptoms [1–7]. The course of schizophrenia is life-long. The illness may have a precipitous onset in the late teens and early adult years followed by an episodic course sometimes with satisfactory recovery between episodes. Often other patterns of illness occur with an insidious onset, partial recovery, or a remarkable lack of recovery between episodes [8, 9]. In most affected individuals, a profound deterioration in psychosocial function occurs within the first few years of the illness [10] and then settles at a low, flatter plateau. Surprisingly, symptoms can improve in later life after 50 years of age. The Vermont study found considerable heterogeneity in outcome in later life, including frank late improvers [11, 12]. These data are consistent with several other outcome studies in Europe and the United States which report frequent good outcome in later years for individuals with schizophrenia [8, 9, 13, 14] even though divergent descriptions exist [15]. It is not known if this is due to the later years being less demanding or if the normal aging process is therapeutic in the illness. Nonetheless, the disease course of schizophrenia can be easily distinguished from traditional neurodegenerative disorders where the course is progressively downhill, such as Parkinson's disease or Alzheimer's dementia, and from traditional neurodevelopmental disorders, such as mental retardation, where the course is low and steady from early years.

The prevalence of 1% in the general population, 9% in siblings of an affected individual, 12% in offspring, and 40–50% in identical twins [16] speaks to a genetic

influence, but one that does not inevitably result in schizophrenia. Schizophrenia can also occur without any family history. Several epidemiological factors have been associated with a predisposition to schizophrenia, including prenatal maternal illness during the second trimester, perinatal birth complications, and winter births [17, 18]. Each risk factor confers a modest risk alone with genetics being the strongest risk factor. Environmental factors contribute to risk, such as adolescent use of cannabis in genetically susceptible individuals [19]. Possibly when they occur together, these risks may be multiplicative. Moreover, the risk factors as a group suggest the importance of early life events in the onset of an illness whose florid symptoms appear much later in life.

Several meta-analyses have demonstrated the clustering of symptoms into at least three distinct symptom domains in schizophrenia: (1) *positive symptoms*, including hallucinations, delusions, thought disorder, and paranoia; (2) *cognitive dysfunction*, especially in attention, working memory, and executive function; and (3) *negative symptoms* such as anhedonia, social isolation, and thought poverty [1–7].

When clinical symptoms are related to imaging findings, specific brain areas are found to be differentially involved in symptom manifestations in schizophrenia. Whether these regionally specific changes are a cause or effect of the disorder is not known, but they do suggest the presence of distinct neuroanatomical substrates, possibly distinct cerebral systems, for the different symptom clusters. Accordingly, we will address these clusters as distinct entities—psychosis, cognitive dysfunction, and negative affect.

7.2.1 Psychosis

7.2.1.1 Phenomenology. Psychosis reflects a loss of touch with reality and distortion of mental functions [20]. These include delusions (distortions in thought content), hallucinations (distortion in perception), disorganized speech (distortions in language and thought process), and disorganized behavior (distortion in self-monitoring of behavior). Delusions are among the most common of the schizophrenia symptoms. They are experiences that persons with schizophrenia believe in fervently although they have no basis in fact. Common examples are delusions of persecution, in which they feel that they are being plotted against, spied on, or intentionally victimized. They may also exhibit paranoia. Other delusions may include those such as grandiosity and religiosity. Bizarre delusions are those that are clearly implausible. Hallucinations may occur in any sensory modality with auditory hallucinations being the most common. These are usually perceived as voices distinct from their own thoughts and often occur as two or more voices conversing with one another or voices maintaining a running commentary on the person's thoughts or behaviors. Disorganized thinking is another key symptom and is evaluated on the basis of the individual's speech. Schizophrenics may rapidly switch from one topic to another lacking a logical connection (loose association), making it difficult to follow their train of thought. A single, unimportant word to the listener may become the focus or topic of the next sentence. The subjects, however, believe that they make perfectly good sense. In severe disorganization, the person may be incomprehensible. Disorganized behavior may manifest in any goal-directed behavior leading to difficulty performing routine daily activities such as preparing a meal or taking a shower. The person may appear disheveled, dress peculiarly, or display inappropriate behavior.

7.2.1.2 Treatment. Antipsychotic drugs have vastly improved the lives of those afflicted with schizophrenia, although they still suffer considerable residual symptom burden and life-long psychosocial impairments. The conventional antipsychotics (butyrophenones, phenothiazines, and thioxanthenes) with potent antidopaminergic activity were used successfully to treat psychosis for 50 years, albeit with acute and chronic motor side effects. In 1990, newer drugs were introduced with higher antiserotonergic potency accompanying the dopamine receptor blockade. These drugs were less likely to cause motor side effects and dysphoria but have their own serious side effects. The metabolic syndrome (weight gain, hyperlipidemia, diabetes, hypertension) is a side effect of concern with many of the new antipsychotics. Clozapine remains the only antipsychotic with demonstrably greater antipsychotic efficacy; the mechanism of its better effect is still not known.

7.2.2 Cognitive Dysfunction

7.2.2.1 Phenomenology. The core symptoms of schizophrenia are of a cognitive nature. The particularly prominent cognitive deficits are working memory defects, attentional dysfunction, verbal and visual learning and memory, processing speed, and social learning [21–26]. No cognitive domains are entirely spared, and deficits in performance are highly intercorrelated within persons [27]. However, schizophrenic subjects in many of the studies show a particular profile of deficits that rules out the lack of motivation as a factor in performance. Neuropsychological characteristics of schizophrenia have not served to localize disease pathophysiology. For example, in schizophrenic persons, memory deficits for recurring digit occur that are consistent with temporohippocampal dysfunction [21]. Functions that are ascribed to frontal cortex are abnormal (e.g., verbal fluency, spatial performance, pattern recognition), and long-term memory is affected. Besides, persons with schizophrenia also perform tasks poorly that require sustained attention or vigilance characteristically associated with the anterior cingulate [28]. Deficits in memory possibly involving the hippocampus occur, including explicit memory, verbal memory, and working memory [29, 30]. Deficits in working memory may explain a part of the disorganization and functional deterioration observed in the illness, since the ability to hold information “on-line” is critical for organizing future thoughts and actions in the context of the recent past [31]. These characteristics of cognition in schizophrenia suggest broad cortical dysfunction.

7.2.2.2 Treatment. Existing treatments of schizophrenia have generally been unsuccessful in treating cognitive deficits in schizophrenia. There is controversy over whether second-generation antipsychotics improve cognition more than classical antipsychotics [32–34]. The MATRICS program was developed to identify potential molecular targets to treat cognitive deficits in schizophrenia [35]. Those targets judged to be most promising include a D_1 dopamine agonist [36], an α_7 nicotinic agonist [37], muscarinic agonists [38], serotonin 5-HT_{1A} and 5-HT_{2A} [39] ligands, noradrenergic agonists, [40] and modulators of the glutamate-sensitive *N*-methyl-D-aspartate (NMDA)-gated ionophore [41]. The metabotropic glutamate receptors mGluR 2, 3, and 5 modulate NMDA receptor function and may also provide a means to enhance cognition [42]. These drugs to improve cognition in schizophrenia are proposed as co-treatments and not as alternatives to current antipsychotics. Thus they will be tested in volunteers whose positive symptoms are optimally treated and

stable. For example, some current strategies being tested include atomoxetine, a norepinephrine (NE) reuptake inhibitor that increases norepinephrine and dopamine levels in the frontal cortex, and M_1 muscarinic agonists (*N*-desmethyl clozapine, a derivative of clozapine with M_1 agonist properties).

7.2.3 Negative Affect

7.2.3.1 Phenomenology. In general, negative symptoms reflect a diminution or loss of normal functions [20]. Affective flattening, alogia, and avolition are prominent features of schizophrenia. Affective flattening is common in schizophrenia and is characterized by the person's face appearing immobile and unresponsive. The range of emotional expressiveness is diminished. Alogia, the poverty of speech, is manifested by short, empty replies. This is due not to unwillingness to speak but rather to diminution of thoughts resulting in decreased fluency and productivity of speech. Avolition is characterized by an inability to initiate and persist in goal-directed activities. The person may sit for long periods of time without showing any interest in participating in work or social activities. These subjects also have poor eye contact and reduced body language. One caveat to keep in mind is that negative symptomatology may be secondary to other factors. For this reason, it is useful to divide negative symptomatology into primary negative symptoms (or deficit symptoms) and secondary symptoms. Primary negative symptoms are the manifestations of schizophrenia and may be complicated by secondary negative symptoms that may occur because of depression, paranoia, or medication side effects. Certain antipsychotics produce extrapyramidal side effects such as bradykinesia that may mimic affective flattening. Comorbid depression can be distinguished by the presence of other symptoms of depression not found in schizophrenia. Paranoia can cause subjects to stay in a room and not talk to people, which can be mistaken as social isolation.

7.2.3.2 Treatment. Specific treatments are not available for primary negative symptoms. Antipsychotic drugs can diminish negative symptoms—an effect that may be secondary to the reduction of acute psychosis. Some studies suggest that the second-generation drugs are effective for secondary negative symptoms but they have shown no efficacy for the deficit symptoms [43]. In a longitudinal study, clozapine was found to be ineffective in treating deficit symptoms [44]. Initial promise of glutamatergic agents such as D-cycloserine [45, 46] has not been replicated in the latest larger multicenter study [47].

The clustering of symptoms and differential response of each symptom domain to medication are consistent with the concept of specific neural substrates for each cluster. While we have an understanding of the pharmacology of receptors targeted by antipsychotic medications, we do not know the cerebral mechanisms of actions of these drugs. It is probable that modulation of receptors at the cellular level can result in functional changes at the neural network level.

Systems biology concepts [48] are beginning to be applied to schizophrenia. Systems neuroscience, the study of the function of neural circuits, is concerned with the functional organization and processing of information in cellular networks, thereby linking molecular and cellular biology to behaviors such as cognitive, motivational, perceptual, and motor processes. In schizophrenia, specific neural

networks may underlie each of the symptom domains. The degree of dysfunction in neural systems may vary and predominantly affected systems may have greater impact on the clinical presentation. The notion is that there are abnormal networks, not just an abnormal protein, in schizophrenia. This neural system-based approach provides a plausible and scientifically sound framework in which to conceptualize the pathophysiology of schizophrenia. We expand on this concept in the next section.

7.3 BIOLOGICAL MECHANISMS

7.3.1 Human Brain Imaging

Advances made in neuroimaging modalities allow regional *in vivo* observations of brain structure, chemistry, and function in persons with schizophrenia.

7.3.1.1 Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) provides structural images of the brain with excellent cross-sectional anatomical detail and strong grey/white matter contrast. MRI studies report a reduction in overall brain size, an increase in ventricular size, and variable cortical wasting in schizophrenia [49–52]. These reports confirm and extend older literature using the computerized axial tomography (CAT) examination of schizophrenia that demonstrated ventricular enlargement [52]. More recently, MRI studies have reported a volume reduction in medial temporal cortical structures (hippocampus, amygdala, and parahippocampal gyrus) [53–57], thalamus [58], and striatum [59, 60]. New analytic techniques for shape analysis show regional shape differences of hippocampus [61] and thalamus [58] in schizophrenia. The volume of the superior temporal gyrus may be reduced in schizophrenia, a change that correlates with the presence of hallucinations [55, 62] and with regional electroencephalographic (EEG) changes [63]. Reduced volume [64–66] and cortical thinning [67] of the cingulate have been described. Frontal lobe abnormalities have been debated with studies showing reduction in volume [68, 69] or no change [70, 71]. The suspicion that a portion of these findings could be caused by antipsychotic treatment was raised by the results of a recent study showing haloperidol-associated increases in ventricular size and decreases in neocortical mass in first-break schizophrenia over the first three months of treatment in a study where second-generation drug treatment produced none of these alterations [72]. The extent to which the overall volume of a brain structure reflects any internal pathology, especially if the pathology is subtle, is necessarily limited. Also, while positive MRI data identify a brain area for further study, negative results do not rule out areas as pathological.

7.3.1.2 Magnetic Resonance Spectroscopic Imaging. Magnetic resonance spectroscopy (MRS) imaging allows measurement of chemical concentrations. Each metabolite is identified by its unique position on a frequency spectrum of multiple peaks; the area under each peak provides a measure of the concentration of the metabolite. Proton MRS (^1H MRS) studies show decreases in *N*-acetyl aspartate (NAA) in the prefrontal cortex [73–75] and temporal lobe [76–80] while others show insignificant trends or no difference [81, 82]. Similarly, reductions of NAA are seen in the anterior cingulate [83] but not in all studies [84]. NAA, found exclusively in

neurons, has been speculated to reflect neuronal integrity. Phosphorous MRS (^{31}P MRS) data reflect the integrity of neuronal cell membranes. Decreased phosphomonoester resonance (precursors of membrane phospholipids) and increased phosphodiester resonances (breakdown products) in the prefrontal and temporal cortices in schizophrenia are postulated to reflect an increased turnover of membranes, possibly due to abnormalities in synaptic pruning [75, 85].

7.3.1.3 Functional Brain Imaging: fMRI and PET. Functional MRI with BOLD (blood-oxygen-level dependent) provides dynamic physiological information and includes the BOLD technique. This technique indirectly measures changes in regional blood flow (rCBF) which reflects regional activity. Positron emission tomography (PET) imaging involves the use of a radioactive tracer to measure rCBF metabolic activity, using O-15 water or F-18 FDG (fluorodeoxyglucose), or to quantify receptors using specific radioligands.

Early PET studies with FDG reported a relative hypometabolism in frontal cortex, a finding consistent with even earlier single-photon-emission computerized tomography (SPECT) blood flow studies [86, 87]. Subsequent PET/FDG studies in schizophrenia produced inconsistent detection of frontal cortex hypometabolism, with some studies continuing to find it [88], others reporting no change in the measure [89], and still others finding frontal hypermetabolism [90]. However, a recent meta-analysis suggests that hypofrontality at rest is found in schizophrenia [91]. Still, there exists two potential confounds. First is antipsychotic drug treatment since neuroleptics are known to reduce neuronal activity in the frontal cortex. Second, deficit symptoms in schizophrenia are associated with reduced frontal cortex activation and could serve to confound observations. Studies have certainly confirmed frontal cortex alterations in schizophrenia with variable, complex, and still incompletely understood characteristics.

7.3.1.3.1 Psychosis Neural Network. Some investigators have suggested altered functional connections between brain regions as the cause of abnormal rCBF patterns seen in schizophrenia [89, 92, 93]. We and others have found evidence for limbic abnormalities in schizophrenia both at rest [89] and with cognitive challenge [94–96]. FDG PET scans at rest showed glucose utilization (rCMRglu) differences between normal and positive-symptom schizophrenia groups in the anterior cingulate cortex (ACC) and the hippocampus (HC) [89]. A follow-up study of similar design tested the regional associations of positive symptoms and showed that as long as patient volunteers were medication free, there was a significant association between rCMRglu in the limbic cortex (ACC plus HC) and the magnitude of positive symptoms in the illness; this correlation was not obtained when patients were medicated or with other symptom domains [97]. These studies allow us to speculate that it is the limbic cortex which is associated with the positive symptoms of the illness, while the PFC may support negative and/or cognitive symptoms. Blood flow changes in the anterior cingulate and adjacent medial frontal cortex also correlate with induction of positive symptoms with the NMDA antagonist ketamine [98]. PET scanning in hallucinating schizophrenic persons is associated with activations in several brain regions, including the medial prefrontal cortex, left superior temporal gyrus (STG), right medial temporal gyrus (MTG), left hippocampus/parahippocampal region, thalamus, putamen, and cingulate [99, 100].

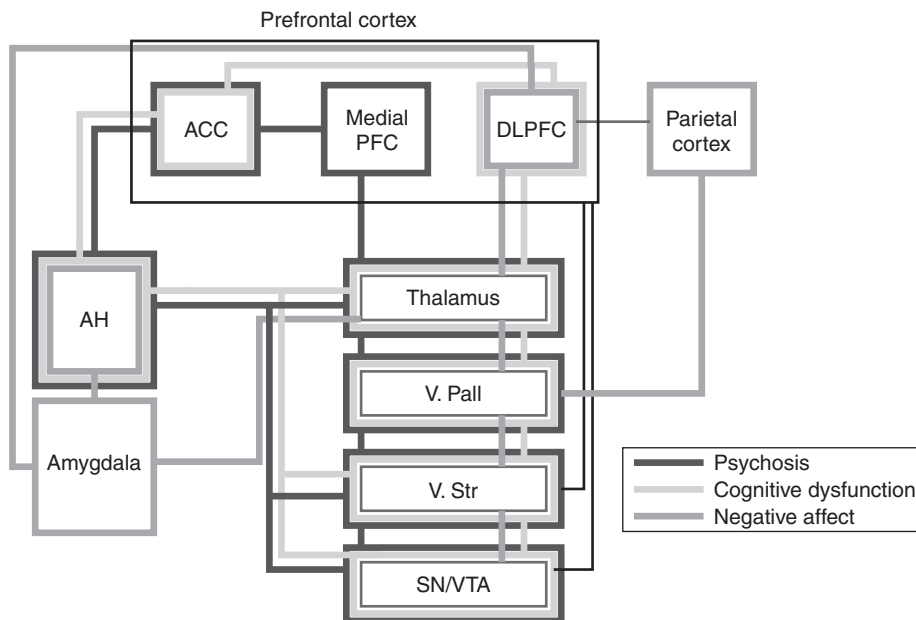

Figure 7.1 Schematic of hypothetical neural systems underlying the three symptom domains: psychosis, cognitive dysfunction, and negative affect. AH = anterior hippocampus; ACC = anterior cingulate; PFC = prefrontal cortex; DLPFC = dorsolateral prefrontal cortex; V. Pall = ventral pallidum; V. Str. = ventral striatum; SN/VTA = substantia nigra/ventral tegmental area. (See color insert.)

These studies provide clues to the anatomic structures that may be involved in a “psychosis neural circuit”. Limbic regions, in particular, are frequently implicated in these *in vivo* studies. Taking these data along with anatomic considerations, we postulate that a neural system for the psychosis cluster in schizophrenia consists of the anterior hippocampus, anterior cingulate, medial PFC (BA 32), thalamus, ventral pallidum striatum, and SN/VTA (see Fig. 7.1). We postulate that the core pathology lies in the hippocampus, resulting in hippocampal dysfunction affecting other regions in the network (e.g., the ACC and medial PFC).

7.3.1.3.2 Negative Affect Neural Network. Brain activation patterns associated with negative symptoms have been studied. Hypoactivation of the frontal lobe is seen with increased negative symptoms in schizophrenia [68, 101–104]. Decrease in rCBF is observed in the prefrontal and parietal cortex among patients exhibiting negative symptoms [89, 105–107]. It is interesting to note that the DLPFC and parietal cortex have dense reciprocal interconnections [108]. Another study in predominantly negative-symptom patients implicates the medial prefrontal, dorsolateral, and prefrontal cortices [109]. Lower activity was also noted in the thalamus [89], in particular the mediodorsal nucleus of the thalamus [110]. The amygdala, a key component in the circuit of emotion, is implicated in emotional processing in schizophrenia [111]. The neural system we propose for the negative-symptom cluster includes the DLPFC, parietal cortex, amygdala/anterior hippocampus, thalamus, ventral pallidum, striatum, and SN/VTA. Of interest, deficit-symptom persons with

schizophrenia exhibit greater impairment in cognitive performance [112, 113] that may reflect overlapping systems.

7.3.1.3.3 Cognitive Deficit Neural Network. In studies of verbal fluency [114] and semantic processing [115], network analysis reveals a functional disconnection between the anterior cingulate and prefrontal regions of schizophrenic subjects. Frontal lobe functional connectivity is abnormal in the schizophrenic subjects even though they had significantly activated the regions and their behavior on the tasks was not impaired. These findings suggest that the abnormalities seen in the frontal lobes of schizophrenics may be due to a problem of integration across regions and not a single regional abnormality. Functional MRI studies using cognitively demanding tasks, such as working memory tasks, produce diverse results. Manoach et al. [116, 117] used the Sternberg item recognition working memory paradigm, which required the subjects to remember either two or five digits. Unlike many PET studies of working memory, they found an increase instead of a decrease in prefrontal rCBF in the schizophrenic volunteers as compared to the normal controls. Callicott et al. [118] using the N-back task and Stevens et al. [119] using the word and tone serial position task found decreases of rCBF in inferior frontal regions of schizophrenic subjects. The task performance of the schizophrenic subjects was significantly worse on the N-back and word serial position task but was matched on the tone task. Research has shown that although rCBF increases in prefrontal regions with greater working memory demands, if working memory capacity is exceeded, the activation decreases [120]. Manoach suggests that the discrepant findings in schizophrenia may be explained by an overload of working memory in schizophrenic subjects for some tasks. In separate studies, disorganization was associated with flow in anterior cingulate and mediodorsal thalamus [106] while apomorphine, a dopamine agonist that has antipsychotic properties, normalizes anterior cingulate blood flow of schizophrenic persons during verbal fluency task performance [121]. We propose that a neural system for cognitive deficits involves the DLPFC, anterior hippocampus, anterior cingulate, thalamus, ventral pallidum, striatum, and SN/VTA (Fig. 7.1).

7.3.1.3.4 Neuroreceptor Imaging. Neuroreceptor PET and SPECT imaging allow direct assessments of receptor density and estimations of neurotransmitter release in the living brain. Human brain imaging ligand studies suggest abnormalities in D_1 receptor density in the frontal cortex of persons with schizophrenia [122, 123] leading to speculation that an agonist at the D_1 receptor may be therapeutic in treating cognitive dysfunctions in schizophrenia [124]. Imaging studies with D_2 dopamine receptor ligands reported increases in D_2 family receptors in neuroleptic-naïve and neuroleptic-free schizophrenia [125], and a later report suggested its presence in psychotic nonschizophrenics [126]; however, subsequent studies using various other D_2 ligands and replications with the initial ligand have been unable to replicate this finding [127–130]. All schizophrenic individuals do not have increased D_2 family receptors in the striatum, but an alteration in D_2 density may be characteristic of a subgroup of schizophrenic patients, perhaps those with a long duration of illness or other special clinical characteristics [131]. The question remains whether D_2 family receptors are elevated in a subgroup of schizophrenic patients or reflect a confound of medication effect in the initial report. More recently, Laruelle et al. [132] measured

dopamine release into the synapse using SPECT or PET imaging with low-affinity dopamine receptor ligands. They report that persons with schizophrenia have an increased release of dopamine in the striatum during the acute phases of their illness in response to amphetamine challenge compared to healthy controls [133]. A significant correlation was seen with dopamine release in the striatum and psychosis but not negative symptoms. Increased release seems not secondary to chronic antipsychotic treatment, since augmented release also occurs in first-episode patients and some family members [134]. This increase in dopaminergic tone in the striatum appears, at least in part, to be under glutamatergic regulation [135, 136]. Imaging glutamate receptors is of keen interest but is hampered by the difficulty in synthesis of such ligands, although efforts are underway [137].

Functional imaging studies have provided the most direct data on neural substrates associated with the symptom clusters while neuroreceptor imaging studies allow in vivo determination of specific receptor abnormalities and indirect measures of neurotransmitter release in specific brain regions. These studies in schizophrenic volunteers can provide in vivo data on molecular abnormalities in specific neural systems. In this section, we have proposed neural systems that may underlie each of the symptom clusters.

7.3.2 Human Post Mortem

7.3.2.1 Structural. Schizophrenia lacks identifiable neuropathological lesions such as occur in Parkinson's disease or Alzheimer's dementia. The pathology is subtle. Numerous studies utilizing a variety of techniques cite decreases in cortical thickness, abnormalities of cell size, cell number and packing density, area, neuronal organization, gross structure, and neurochemistry [138–140]. These data, however, have not been consistently replicated across laboratories, making it difficult to build a consistent story across all of the findings. This may be due to differences in patient populations, stage of illness, and medication status, although possible confounds of tissue artifact, agonal state, chronic drug treatment, lifelong-altered mental state, and relevant demographic factors must always be considered in evaluating postmortem brain tissue studies.

7.3.2.2 Neurochemical. Neurochemical studies began in schizophrenia at a time when scientists were anticipating a single protein defect. While no single defect has been found, investigators interpret studies in a broader systems context. Nonetheless, findings are often still organized by neurotransmitter system.

Studies of biochemical markers of the dopamine system in schizophrenia were stimulated by the early pharmacological observation that blockade of dopamine receptors in the brain reduces psychotic symptoms [141]. The hypothesis derived from this observation that dysfunction of the dopaminergic central nervous system (CNS) either in whole or in part accounts for psychosis in schizophrenia has been explored in all body fluids and in various conditions of rest and stimulation over the last half century [142, 143], with little real support except for the recent imaging studies that show higher occupancy of D₂ receptors by dopamine (DA) in patients with schizophrenia [144] and changes in DA release in acute illness phases [134].

More recently, because of its ubiquitous and prominent location in the CNS and because the antiglutamatergic drugs phencyclidine (PCP) and ketamine cause a

schizophrenic-like reaction in humans, the glutamate system has become a focus of study. Several studies have examined ionotropic glutamate receptor subtypes [145]. Most studies have focused on the mesial temporal lobe and, in general, report abnormalities in α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), kainate (KA), and NMDA receptor expression at the messenger RNA (mRNA), protein, and ligand binding level. In the prefrontal cortex, results are inconsistent, although recent studies report AMPA abnormalities [146, 147]. Changes are also reported in ionotropic receptor [148] and PSD 95 expression [149] in the thalamus. Few studies have examined the metabotropic glutamate receptors (mGluRs) in schizophrenia. Group II (mGluR2 and 3) receptors are implicated in animal [150] and human [151] studies. *N*-acetylaspartylglutamate (NAAG), an endogenous agonist of mGluR3 [152, 153], and its metabolic enzyme [154, 155] are abnormal in schizophrenia. Additionally, mGluR3 may be a risk gene for schizophrenia [156].

Evidence of γ -aminobutyric acid (GABAergic) involvement is found in reduced expression of presynaptic markers in subpopulations of interneurons in the frontal cortex and the hippocampal formation [157, 158]. GABAergic neurons can be defined by the presence of one of three calcium binding proteins, namely parvalbumin, calretinin, and calbindin. The most characteristic morphological types of neurons that express parvalbumin are the large basket and chandelier cells [159]. GAD 67 and GAT1 are decreased in the parvalbumin-expressing prefrontal interneurons [160].

The affinity of newer antipsychotic drugs for serotonergic receptors has raised speculation over the role of this neurotransmitter system in the treatment and perhaps in the pathophysiology of the illness. Years ago, serotonin was hypothesized to be central to the pathophysiology of schizophrenia, because of the psychotomimetic actions of serotonergic drugs, such as lysergic acid diethylamide (LSD) [161]. Postmortem studies have failed to find consistent change in measures of the serotonin system in schizophrenia, including in receptors (in vivo and postmortem) or in metabolites [162]. Since serotonin has been shown to modify dopamine release in striatum [163, 164], the augmented antipsychotic action of the new drugs may be mediated through modulation of dopamine release into the synapse. Indeed, drugs without any dopamine receptor affinity but with only 5-HT_{2A} receptor antagonism do behave as antipsychotic drugs in animal models and show antipsychotic activity in humans [165]. Since the serotonin system has diverse receptors and functions, it is not surprising that this aspect is not yet fully explicated.

Cholinergic neurotransmission, integral to cognition and memory, may be dysfunctional in schizophrenia. Clinically, it is well known that schizophrenic patients have a much higher incidence of cigarette smoking [166]. Although "control" smokers exhibit an upregulation in nicotinic receptors [167, 168], decreased levels of nicotinic and muscarinic receptors are reported in the hippocampus frontal cortex, thalamus, and striatum in schizophrenia [169].

Molecular abnormalities are found in a number of anatomic regions and in several neurotransmitter systems in the neuropathology of schizophrenia. Abnormalities in molecular targets should be examined in terms of pathways (not only neurotransmitter pathways) affecting circuit function. Additionally, identification of primary pathology from epiphenomenon is essential. For example, neurotransmitter systems are dynamic and disruption of one system would lead to compensatory mechanisms in other relevant pathways. In general, a strategy to follow once a positive finding is

made would be to confirm the finding is real and not an artifact, replicate the finding in another cohort, and determine if the molecular abnormality is part of the primary pathology. Converging data from in vivo human studies, post mortem human studies and animal model studies would provide clues to the primary pathology.

7.3.3 Genetics and Phenotypes

Schizophrenia is heritable but does not follow a simple pattern. Multiple susceptibility genes, each of small effect, are believed to exist for schizophrenia. Replicated linkages to several chromosomal regions have been made, including to 8p, 22q, 2, 3, 5q, 6p, 11q, 13q, and 20p, and there are several genes within these regions that have been associated with the illness, including neuregulin (*NRG1*) [170], dysbindin (*DTNBP1*) [171], *G72* [172], D-amino-acid oxidase (*DAAO*), regulator of G-protein signaling 4 (*RGS4*) [173], proline dehydrogenase (*ProDH*) [174], catechol-*O*-methyl transferase (*COMT*) [175, 176] and metabotropic glutamate receptor 3 (*mGluR3*) [156]. Each of these genes codes for a protein that has been speculatively linked with a purported illness mechanism [177, 178], but no clear disease pathophysiology has yet emerged. The goal of confirming a susceptibility gene for schizophrenia is to acquire molecular information about disease mechanisms, which could potentially lead to a broader understanding of the illness and be a basis for novel treatment development.

Investigators argue that an important impediment in understanding the neurobiology of schizophrenia is disease heterogeneity. This may account for the lack of firm knowledge of disease pathophysiology that is the biggest impediment to progress in therapeutics. Therefore, investigators have been attempting to define more homogeneous phenotypes of schizophrenia in persons with the illness and in family members ("endophenotypes") to test these genetically [17]. The features most often used to develop phenotypes in the illness are neurocognitive characteristics, eye movements [179–181], prepulse inhibition (PPI) [182, 183], evoked potential [184], and in vivo brain imaging features (reviewed in Gottesman and Gould [185]). These are spontaneous behaviors of the brain occurring in response to external cues that have a known neural anatomy, and hence may be more direct reflections of neural pathology [186]. The ability of some probands (60–70%) with schizophrenia to follow a smooth pendulum movement with their eyes is deficient [187]. Instead of describing smooth movements following a pendulum stimulus, some show jerky and irregular (delayed and catch-up movements) tracking patterns. Also, antisaccade eye movements (those directed away from a stimulus) are also abnormal in persons with the illness [187, 188]. PPI is a normal phenomenon evident across all sensory modalities, where a small initial ("pre") stimulus decreases the electrophysiological response to a second higher intensity stimulus. In schizophrenia, many probands show abnormal PPI, as do unaffected family members. The neural systems influencing both oculomotor movements and PPI have been well described in the animal and are believed to be highly conserved in the human [189, 190]. P50 is an electrophysiological measure produced when two equal auditory stimuli are presented 500 ms apart and their evoked potential is measured. Healthy persons show a reduced response (in amplitude) to the second signal whereas persons with schizophrenia (estimated at 80%) show less or no suppression.

These data will help identify candidate genes and allow rational selection of molecular targets for further investigation. Although genetic involvement in schizophrenia is

certain, genetic makeup alone does not predict schizophrenia. Also schizophrenia typically does not manifest until the second or third decade of life, implying an interaction between genotype and other factors prior to onset of the illness. It is possible that as the brain matures (e.g., during adolescence) neural networks in the brain are developing and becoming established, a time when molecular abnormalities may become apparent.

7.4 ANIMAL MODELS

Schizophrenia, as we know it, is a uniquely human disorder; therefore creating an exact or full animal model of this illness may not be possible. It is, however, possible to create models to study aspects of disease etiology or pathophysiological mechanisms and to create models for target symptom areas. Approaches include genetic manipulations, pharmacological and environmental manipulations, and discrete anatomic lesions. These animal models produce symptoms that qualify as belonging to one or more of the three symptom clusters.

7.4.1 Cognitive Deficit Model

7.4.1.1 *Working Memory Deficits.* The limited cognitive capacity of animals limits the design of cognitive tasks. Olton and Samuelson [191] devised a classic task for assessing memory in the rodent, the radial arm maze. Delayed alternation problems capitalize on the rats' tendency to choose alternative maze arms or locations when rats are reexposed to an apparatus, the most common version is the T maze. Delayed nonmatching to sample tasks require a rat to remember a stimulus over a delay in which that stimulus is no longer present. Nonhuman primate working memory models include spatial delayed response, delayed match to sample, and attentional set-shifting tasks [192].

7.4.1.2 *Declarative Memory Deficits.* Explicit or declarative memory is abnormal in schizophrenia [193–195]. This is hippocampal dependent and has been examined in animal models. The role of the hippocampus in learning and memory tasks that encourage animals to compare and contrast odor items as they learn about them and to encode both direct and indirect relations among odors has been described [196]. Transitive inference (TI), a task of the ability to infer a relationship between items that have not been presented together, is abnormal in schizophrenia [197] and can be tested in rodents [198].

7.4.1.3 *Attention Deficits.* The continuous performance test (CPT) developed by Rosvold et al [199] is a paradigm used to test attention in schizophrenia. Subjects continually monitor the location of a brief visual target in one of five spatial locations that occur randomly [200], providing a measure of visuospatial attention. An analogous test for use in rodents is the five-choice serial reaction time task [201]. This test has been used to examine effects of drugs and neuroanatomical lesions on various aspects of attentional performance, including selective attention, vigilance, and executive control [202, 203].

7.4.1.3.1 Social Interactions. Social withdrawal is a significant feature in schizophrenia. Dyadic encounters have often been used to investigate social behavior in rats [204, 205]. Social recognition is assessed by quantifying the duration of social investigation during subsequent exposures to the same individual. Reexposure is characterized by a shorter investigation time. This foreshortened time is taken to represent the social recognition. Social cognition is a particular aspect of learning and memory that is selectively impaired in schizophrenia [206]. In rats, ketamine disrupts social learning, an effect that can be reversed by antipsychotic treatment [207]. The prairie vole provides another model to study social interactions. These rodents are highly social, form selective, enduring pair bonds with one mate [208, 209], and are amenable to experimental manipulation.

7.4.2 Genetic Models

A number of mutant mice for several neuroreceptors have been developed, including those for NMDA receptor subunits [210], mGluR1 [211], mGluR5 [212], dopamine receptor subtypes [213], and adrenergic α_{2A} receptors [214]. Of these, the most interesting mutant mice are those deficient in NMDA glutamate receptors generated by targeted mutation of the crucial NR1 subunit gene [210]. NR1 knockout mice display increase in activity and stereotypies that were attenuated by antipsychotic treatment. They also exhibit negative symptoms evidenced by the decrease in social interactions. These behaviors are similar to those observed in the PCP or MK-801 treated animals. Mutants for the transcription factors NPAS1 and NPAS3 have been reported to result in PPI deficits, impaired social recognition, and locomotor abnormalities [215].

7.4.3 Psychosis Model

Pharmacological models designed to perturb a particular neurotransmitter system have been described. These models induce “psychosis” but not exclusively:

1. *Glutamatergic Models* NMDA receptor antagonists, such as PCP and ketamine, induce psychotic symptoms in healthy humans [216–219] and exacerbate psychotic symptoms in patients with schizophrenia [220]. It is also found to disrupt PPI, an effect that can be reversed by atypical antipsychosis [221, 222]. In rodents, PCP administration induces behavioral activation observed as hyperlocomotion and stereotypies (positive symptoms) [223–229], impaired performance on learning and memory processes (cognitive deficit cluster) [230], and diminished social interactions (negative-symptom cluster) [229–231]. These effects can be reversed by mGluR2/3 agonists [150, 232].

2. *Dopamine Agonist Models* Hyperactivity of the mesolimbic dopaminergic system and hypoactivity in the frontal cortex have been postulated as producing positive and negative symptoms, respectively, in schizophrenia [233]. Similar to the effects of NMDA antagonists, amphetamine induces psychotic reactions in normal individuals and exacerbates symptoms in schizophrenic patients [234, 235]. Negative symptomatology, however, is not reproduced by amphetamine administration [236].

3. *Cannabinoid Model* Administration of Δ^9 -tetrahydrocannabinol (Δ^9 -THC), the major active component in cannabis, transiently increases positive and negative symptoms and cognitive deficits in healthy human volunteers and subjects with schizophrenia [237]. The *val/met* functional polymorphism in the *COMT* gene influences the development of psychosis in adolescent marijuana users [19]. Carriers of the *val158* allele, but not the *met* carriers, were much more likely to develop symptoms of psychosis. This suggests an interaction between genetic predisposition and environmental factors. In rats, Δ^9 -THC influences cognitive and behavioral functions in rats [238–241].

7.4.4 Neurodevelopmental Model

7.4.4.1 Disruption of Neurogenesis. This model aims to disrupt normal cell division and maturation at specific gestational time points in an attempt to reproduce abnormalities found in schizophrenia. Prenatal injection of the mitotic inhibitor methylazoxymethanol (MAM) at day E17 produces behavioral changes mimicking the positive and negative symptoms of the disorder. Aberrant cell migration in the hippocampus and a disrupted laminar pattern in the neocortex associated with deficits in working memory [242] and other specific cognitive deficits [243] are observed in these animals. Another approach is the irradiation of monkeys in midgestation which produces cortical abnormalities reminiscent of schizophrenia [244]. Behavioral tests have not yet been reported for these monkeys.

7.4.4.2 Lesion Models. Neonatal ventral hippocampal lesions in rats have been proposed as an animal model [245]. This lesion interferes with development of the hippocampus and its associated connections with other brain regions such as the prefrontal cortex. These animals exhibit some behavioral and molecular changes observed in schizophrenia [246–248]. Lesions in other brain structures like the medial prefrontal cortex [249] have been described.

Animal models in schizophrenia have been criticized as not being definitive. While it may not be possible to reproduce the full syndrome in animals, it does not mean that animal models are not useful or informative about the discrete characteristics they demonstrate. It would be ideal if each symptom cluster and associated neural circuit could be examined separately. Each circuit, however, is not discrete and overlap is present, allowing one circuit to influence the others. Using a number of different animal models targeting specific proteins, pathways, anatomic regions, or circuits and examining the converging data will provide the most useful data.

7.5 CONCLUSION: HOW FAR HAVE WE COME AND WHAT ARE THE REMAINING QUESTIONS?

Schizophrenia is a complex disease most likely associated with multiple etiologies. Clinically, the illness can be identified by its typical presentation, but researchers endeavor to distinguish subgroups within the diagnosis “schizophrenia” in an effort to identify unique pathophysiological mechanisms. The phenotypes of schizophrenia, defined by symptoms, psychological, electrophysiological, biochemical, or physiological

(i.e., rCBF) characteristics, are being proposed. The sorting of these phenotypes into biologically meaningful groups is ongoing. In brain imaging studies, distinct anatomic substrates for the three symptom clusters (psychosis, cognitive dysfunction, and negative affect) suggest the presence of specific neural networks for each cluster. It is possible that endophenotypes identified by electrophysiological or neurocognitive means also share neural network dysfunction.

A shift in conceptual framework from defects in specific proteins to defects in neural networks may represent a biologically relevant mechanism useful in investigating the pathophysiology of schizophrenia. This will require identification of relevant neural systems and an understanding of the dynamics of the systems. Then such systems could be used as a model to test function—what are the effects of disrupting one part of a network? Are there compensatory mechanisms that come into play? Are there regions that are crucial to the functioning of the system? How can we modulate the system in the diseased state to make it more efficient? The system's neuroscience approach in schizophrenia is at its very early stages of conceptualization. As an initial formulation, we propose neural networks for each of the symptom domains (Fig. 7.1). This formulation proposes that the core pathology in the hippocampus influences function of networks involving distinct cortical regions and subcortical structures.

Whether the symptom domains are manifestations of a single disease pathophysiology perturbing the neural networks or are each a partially independent disease construct remains unknown. However, heterogeneity is more often presumed about the illness, certainly with respect to etiology. An integral part of determining function of affected neural systems is understanding the molecular composition of the connections in the network. The primary molecular lesion of schizophrenia or of any one of its subgroups has not yet been identified. Whether productive leads will derive from clinical pharmacology, genetics, imaging, or phenotyping or perhaps from all is a speculation. It is the kind of discovery that will be used to target novel drug discovery. Without known molecular targets, therapeutics can advance only by serendipity, chance, or modifications of existing treatments. Hope for identifying the pivotal molecular targets for schizophrenia rests on the application of modern concepts and techniques to clearly diagnosed and characterized populations of persons with schizophrenia. There are therapeutic implications to heterogeneity: Does one treatment exist for schizophrenia or are there several symptom or syndrome-specific treatments for the illness? This question remains open, but taking clues from other illness, one would guess that several treatments will emerge.

8.1 INTRODUCTION

Discovery of the first generation of antipsychotic drugs in the 1950s is often credited with the birth of neuronally based approaches to explain the etiology and the pathophysiology of schizophrenia. While at the time this discovery presented a major conceptual shift from the Freudian psychosocial approach to explaining schizophrenia, it is important to note that the pre-Freudian ideas about schizophrenia (*dementia praecox*) were eerily similar to our current concepts and understandings of the disease, specifically, that the etiology is dependent on genetic predisposition [1] and that the primary pathophysiology may involve cortical dysfunction [2, 3]. This is apparent in many texts and research papers written on mental illness at the turn of

the century where, in describing the “etiology” of the disease, statements like “in the causation of dementia praecox the hereditary factor is the most important: the other factors are, for the most part, contributory or excitatory” [4, p.16] or “the importance of heredity as a factor concerned in the etiology of schizophrenia has long been recognized” [5, p.77] were the norm. Similarly, the leading pathological theories about schizophrenia by Mott, Kraepelin, and Alzheimer included gliosis of the cortex and dissociated activity of the afferent and efferent neurons causing an imbalance of “pyramidal” activity [6, 7]. Given this historical context, our approach in this chapter on dopamine and glutamate hypotheses of schizophrenia has been to focus on the evolution of these theories. Recent advances in postmortem, imaging, and genetic fields clearly indicate that schizophrenia is not caused by abnormalities in a single gene, a single neurotransmitter or receptor, or a single brain region. Dopamine and glutamate hypotheses of schizophrenia, although narrowly defined at conception, have evolved to accommodate these most recent neuroscientific findings and thus remain two of the most influential theories in the field.

8.2 DOPAMINE HYPOTHESIS

8.2.1 History

The dopamine hypothesis of schizophrenia, in its original form, stated that a hyperactive dopamine transmission is responsible for the psychotic features of the disease [8]. This theory was consistent with the then newly emerged concept that neurochemical imbalances in the brain may be responsible for major psychiatric disorders [9–12]. A few years earlier, clinical studies with chlorpromazine [13] and reserpine [14, 15] had demonstrated, for the first time, the effectiveness of pharmacotherapy in treating psychotic symptoms of schizophrenia. Subsequent animal studies showed that reserpine, which was later found to inhibit the vesicular monoamine transporter protein (VMAT), increased tissue levels of serotonin and norepinephrine (these studies did not assess the levels of dopamine as dopamine neurons had not yet been discovered). These findings led to the hypothesis that schizophrenia was associated with a state of monoamine deficiency and that neuroleptics ameliorated this condition by increasing the release of serotonin and norepinephrine [9]. Upon discovering the dopamine neurons, Carlsson and Lindquist found that chlorpromazine and another antipsychotic drug haloperidol increased the metabolite levels of dopamine, suggesting that these drugs increase the turnover rate of this neurotransmitter [8]. The authors then proposed that this increased turnover was a *compensatory* mechanism that was secondary to the blockade of dopamine receptors. The idea that inhibition of dopamine receptors, as opposed to enhancing monoamine release, mediates the actions of neuroleptics gained acceptance after the identification of two different subtypes of dopamine receptors, D₁ and D₂, and became the prominent theory of the field after the seminal finding that all antipsychotic drugs block the dopamine D₂ receptors with affinities that correlate with their clinical efficacy [16, 17]. Concurrent with these studies, it was found that psychostimulants that increase dopamine neurotransmission, either through release of endogenous dopamine [18–20] or through direct activation of dopamine receptors [21–23], had psychotomimetic properties in nonschizophrenics and exacerbated symptoms in patients with schizophrenia. Together, these findings lend a great

deal of support for Carlsson and Lindquist's initial idea that antipsychotic drugs help to alleviate a hyperactive dopamine system and led to intense efforts to find direct evidence for a disrupted dopamine transmission in schizophrenia. However, the substantial body of research, spreading over five decades, which has been undertaken to address this fundamental issue has not yet provided direct evidence that over-activation of the dopamine system accounts for the spectrum of symptoms that are associated with schizophrenia. But these studies have found many interesting, albeit subtle, changes in some dopamine systems in schizophrenia which have prompted the formulation of more elaborate ideas about dopaminergic abnormalities in schizophrenia.

8.2.2 Pathological Evidence

Over 50 years of intense research has failed to show postmortem dopamine-related abnormalities that would be consistent with a hyperactive dopamine state in schizophrenia. Although several studies have reported an increase in striatal D₂ receptor density in postmortem schizophrenic tissues [24–27], the interpretation of these results is confounded by the fact that chronic antipsychotic treatment can upregulate D₂ receptors [28]. Other dopamine-related findings in postmortem schizophrenic brains include (1) a lack of change in striatal and prefrontal cortex (PFC) D₁ receptor density and messenger RNA (mRNA) levels [29–34]; (2) a reported increase in striatal D₃ receptor number [35] that was not associated with change in striatal D₃ receptor mRNA levels [30]; (3) an increase in striatal D₄ receptor density [36–38] that was not confirmed by other studies [39–41]; (4) a lack of change [42, 43] (but also see [44]) in the expression of D₄ mRNA levels in the PFC; (5) a lack of change in striatal dopamine transporter (DAT) density [33, 45–47]; and (6) unaltered activity of striatal dopamine-related enzymes such as tyrosine hydroxylase (TH), dopamine β-hydroxylase, and catechol-*O*-methyl transferase (COMT) [48]. Moreover, limited and inconsistent changes in the concentration of tissue dopamine and its metabolites have been reported in schizophrenic brains [49, 50]. Collectively, these negative findings have engendered speculations that dopaminergic abnormalities in schizophrenics may involve subtle and activity-dependent abnormalities that cannot be detected in postmortem tissues.

8.2.3 Imaging Evidence

New evidence from in vivo imaging studies has been instrumental in advancing our knowledge of the dynamics of the dopamine systems in schizophrenia. In general, imaging studies have the advantage of allowing investigators to control for the effects of treatment, to correlate the abnormalities with clinical symptoms, and to study the in vivo functional dynamics of dopamine release. For example, imaging studies in untreated drug-naïve schizophrenic patients have addressed the confounding effect of previous neuroleptic treatment on striatal dopamine receptor density. While two studies reported increased striatal D₂ receptor density in schizophrenia [51, 52], a meta-analysis of 17 studies reported a relatively small (12%) increase in the density of these receptors [53], leading to the consensus that it is unlikely that such an inconsistent and weak effect on D₂ receptor density would be the primary cause of schizophrenic pathology. The imaging findings with other dopamine receptor

subtypes have also been inconsistent. For example, a high-profile study reporting an increase in the density of D₁ receptors in the PFC of schizophrenics [54] subsequently was not replicated [55]. On the other hand, interesting and consistent results have emerged from investigations of the functional dynamics of dopamine release in schizophrenia. For example, positron emission tomography (PET) studies following administration of radiolabeled dopamine substrates such as dopa or fluorodopa have shown that patients with schizophrenia have a higher rate of dopamine synthesis than normal controls [56–59]. Others, using PET and single-photon-emission computerized tomography imaging during an amphetamine challenge to assess the release of endogenous dopamine, have found a higher level of dopamine release in response to amphetamine in patients with schizophrenia compared to normal controls [60, 61]. Interestingly, this effect was associated with acute exacerbations of psychotic symptoms but could not be detected when patients were in a phase of symptom stabilization [62]. A recent report of increased baseline occupancy of striatal D₂ receptors in schizophrenics is of special interest [63], though this finding remains to be replicated. Together, these recent findings have strengthened the link between dopaminergic hyperactivity and positive symptoms of schizophrenia [50, 64] but have not established a primary role for dopamine abnormality in this disorder. Another important PET study measured D₁ receptor availability in drug-naïve or drug-free patients and reported that D₁ receptor antagonist binding potential was significantly elevated in dorsolateral PFC of patients with schizophrenia [65]. This measure demonstrated an increased availability of D₁ receptors which would result from reduced, as opposed to increased, dopaminergic neurotransmission. Implications of this dichotomy are discussed later.

8.2.4 Genetic Evidence

Schizophrenia is a multifactorial disease with a complex mode of inheritance [66]. There has been limited convergence of evidence on dopamine-associated genetic loci that may be associated with schizophrenia. Positive reports of D₃ receptor gene polymorphism associated with schizophrenia [67, 68] were not confirmed in other association or linkage studies [69, 70]. Nonetheless, a recent meta-analysis of genetic studies has shown a small degree of association for the D₃ receptor gene [71]. Linkage studies involving genes for other dopamine receptors as well as dopamine related proteins have been mostly negative or ambiguous [69, 72]. One exception, however, involves the gene that encodes for the enzyme COMT. This is an extracellular degradative enzyme that converts dopamine to its aldehyde derivative and, therefore, plays a critical role in regulating the extracellular levels of dopamine [73]. The COMT gene is on 22q11, which is considered a chromosomal “hot spot” for genes that are associated with increased vulnerability to develop schizophrenia [74]. A common functional polymorphism on this gene (Val¹⁰⁸/¹⁵⁸Met) accounts for up to a fourfold variation in enzymatic activity and the subsequent dopamine metabolism. In patients with schizophrenia this polymorphism may predict 4% of the variance in performance on cognitive tasks, such as the Wisconsin card sort task (WCST), that are dependent on the proper functioning of cortical dopamine [75]. Subsequent studies have replicated the effects of COMT genotype on PFC cortical function [76, 77]. However, a recent meta-analysis failed to show a significant association of COMT polymorphism with schizophrenia [71]. While this COMT polymorphism may not

have a substantial influence on the pathophysiology of schizophrenia, its convincing influence on cognitive function suggests that it may contribute to poor cognitive capacity of some patients with schizophrenia [2].

8.2.5 Pharmacological Evidence

In the absence of direct evidence for dopamine hyperactivity in schizophrenia, the pharmacological profile of antipsychotic drugs continues to provide the strongest support for a hyperdopaminergic state in schizophrenia. Imaging studies have established a link between D_2 receptor occupancy and clinical efficacy of antipsychotic drugs (see [78, 79] for review). While all clinically efficacious antipsychotic drugs lead to significant D_2 receptor occupancy, the imaging studies have failed to establish a direct relationship between the degree of striatal D_2 receptor occupancy and the clinical efficacy of antipsychotic drugs [80–82], primarily because ample D_2 receptor occupancy is observed in patients who do not respond to conventional antipsychotic treatment [81]. This fact has reinforced the idea that D_2 occupancy may be necessary but not sufficient for treatment of schizophrenia and has led to suggestions that co-occupation of D_2 with other receptors such as the dopamine D_3 [83] or D_4 [84, 85], the serotonin 5-HT₂ [86] or 5-HT_{1A} [87], and the α -noradrenergic [88] receptors may lead to more efficacious treatment. On the other hand, Kapur and Seeman [89] have argued that optimal modulation of D_2 receptors involving factors such as rate of dissociation, and not complementary actions on other receptors, is the key to clinical efficacy of atypical antipsychotics. In addition to D_2 receptor antagonism, other manipulations of dopaminergic transmission have been explored as potential therapeutic strategies in schizophrenia. Some researchers have attempted to develop a therapeutic strategy based on pure D_4 receptor antagonism [90] primarily because the atypical antipsychotic drug clozapine has preferential affinity for D_4 over D_2 receptors. However, clinical trials with two selective D_4 blockers, sonopiprazole and L-745,870, have been disappointing [90, 91]. Others have suggested that partial D_2 receptor agonists may be used as dopaminergic stabilizers to antagonize the excessive activation of the dopaminergic system without inducing a hypodopaminergic state that has been associated with serious motor and motivational side effects of current drugs [92, 93]. Preliminary studies with the partial D_2 agonist (–)-3PPP have produced positive results [94, 95]. Another drug in this class, aripiprazole, has been approved recently for clinical use and early results on the clinical efficacy and side-effect profile of this drug appear promising [96–98]. Whether this superior profile is mainly due to dopaminergic modulation remains a matter of debate because aripiprazole also modulates serotonin 5-HT_{1A} and 5-HT_{2A} receptors [99]. Interestingly, the selective dopamine D_2/D_3 receptor antagonist amisulpride was recently introduced as the first atypical antipsychotic that does not have a significant affinity for 5-HT_{2A} or other serotonin receptors. Ongoing clinical trials with this drug will allow for a better assessment of the exclusive contribution of dopaminergic effects to the therapeutic profile of antipsychotic drugs [100, 101].

8.2.6 Evolution of Dopamine Hypothesis: Cortical Versus Striatal Dopamine

An increased understanding of the principles that govern higher cognitive functions has led to formulation of more elaborate versions of the dopamine hypothesis of

schizophrenia. This progress has been made in the larger framework of a “systems neuroscience” approach to complex psychiatric disorders, where (1) distinct behavioral components of a clinical syndrome are considered and (2) relevant molecular, cellular, and circuit-based data from “normal” (human or animal) subjects are applied to define mechanisms that subserve these behavioral components. In the context of schizophrenia, applying this approach has been useful in elucidating mechanisms that may underlie the cognitive and negative symptoms of this disorder. The most notable insight has come from studies that have characterized the role of PFC in maintaining cognitive functions that are relevant to schizophrenia. In general, numerous imaging studies have shown that several subregions of the PFC are activated during performance of cognitive tasks that require working memory or set shifting [102–106]. In patients with schizophrenia, which generally exhibit impaired working memory, this task-dependent activation of cortical activity is diminished (see [73] for a review). Seminal work by Goldman-Rakic and coinvestigators has shown that a key neuronal system in the PFC for maintaining working memory is the dopaminergic projection to this region [107–110]. In particular, optimal activation of PFC dopamine D₁ receptors, a subtype that is abundant in the cortical regions [111], appears to be critical for working memory performance (see [112] for a review). These primate studies have been critical in generating the hypothesis that a deficiency in cortical dopamine transmission may underlie the cognitive deficits of schizophrenia [113, 114].

A number of clinical studies also suggest a role for cortical dopamine dysfunction in schizophrenia. For example, a direct relationship between decreased metabolic activity in PFC and reduced cerebrospinal fluid (CSF) concentration of homovanillic acid, the major metabolite of cortical dopamine, has been reported in schizophrenic patients during their performance of cognition tasks [115, 116]. Furthermore, Akil and coinvestigators [117, 118] have reported a significant reduction in the length of cortical axons that are immunoreactive for tyrosine-hydroxylase, a finding that would be consistent with reduced catecholaminergic innervation in the PFC. While the low density of D₂ receptors in the PFC has not allowed for reliable PET measurements with D₂-selective ligands, several studies have reported interesting changes in D₁ receptor occupancy in patients with schizophrenia. The first report was by Okubo et al. [54], who demonstrated a positive correlation between the increased density of D₁ receptors in PFC of patients and performance on the WCST. A more recent PET study using a superior D₁ receptor ligand has reported a contrasting finding of increased, rather than decreased, D₁ receptor binding in drug-free and drug-naïve schizophrenia patients, which showed a positive correlation with performance in a working memory task [65]. Notably, the same investigators have provided evidence from rodent experiments that the clinical findings may reflect a compensatory upregulation of D₁ receptors following sustained dopaminergic depletion, an interpretation that would fit with a deficit in PFC dopamine activity [119, 120].

Collectively, these findings have led to a more elaborate bidirectional dopamine hypothesis proposing that schizophrenia may be associated with a concomitant cortical hypodopaminergia, which presumably contributes to negative and cognitive symptoms of schizophrenia through reduced D₁ receptor activity, and a subcortical hyperdopaminergia, which leads to positive symptoms through overactivation of D₂ receptors [50, 114]. This revised theory offers a mechanism that explains not only psychosis but also the cognitive symptoms of schizophrenia and has

encouraged development of therapeutics that may specifically target these symptoms. Furthermore, this framework has prompted systems-oriented clinical research in schizophrenia which is helping to increase our knowledge of the pathophysiology of the disease. For example, Bertolino and coinvestigators [121, 122] have shown that *N*-acetylaspartate (NAA), an imaging marker of neuronal functional integrity, is negatively correlated, in dorsolateral PFC, with striatal dopamine release in schizophrenia. Meyer-Lindberg et al. [123], using double measures of regional cerebral blood flow and fluorodopa uptake in schizophrenic subjects during performance of the WCST, corroborated the relationship between hypoactivation of PFC and increased striatal dopamine utilization during a working memory task.

Pharmacological studies using dopamine receptor agonists in primates have supported the notion that activation of D₁ receptor function may be useful for treating cognitive deficits in some animal models [124–126]. While therapeutic efficacy of D₁ receptor agonists remains to be validated, this pharmacological strategy has been indirectly tested in several studies demonstrating that administration of nonspecific dopamine agonists, such as amphetamine or apomorphine, to patients with schizophrenia improves working memory performance and PFC signal-to-noise ratio [127–129].

8.3 GLUTAMATE THEORY OF SCHIZOPHRENIA

8.3.1 History

Unlike the dopamine hypothesis, which was not based on actual dopaminergic abnormalities and was formed to accommodate the mechanism of action of antipsychotic drugs, the idea of a glutamatergic hypofunction was first generated because postmortem and CSF data from patients with schizophrenia were suggestive of a dysregulated excitatory amino acid system [130, 131]. This theory, however, did not gain acceptance at the time because, first, subsequent studies did not confirm the findings of Kim and coinvestigators [132–134] and, second, our limited knowledge of the function and behavioral pharmacology of the glutamate system at the time dictated that a dysfunctional glutamate system would result in overt toxicity and developmental abnormalities as opposed to the subtle and regionally specific cellular changes that occur in schizophrenia. A major revival of the glutamate theory occurred with the discovery that the well-known psychotomimetic drug phencyclidine (“angel dust”) is a selective noncompetitive blocker of *N*-methyl-D-aspartate (NMDA) glutamate receptors [135–138]. This agent produces an acute psychotic episode with high resemblance to the spectrum of schizophrenic symptoms and profoundly exacerbates preexisting symptoms of schizophrenia in patients [139–142]. Recent clinical trials using ketamine and analogs, Federal Drug Administration (FDA)–approved blockers of NMDA receptors, have carefully characterized the profile of symptoms induced in healthy subjects by this class of compounds [143–146]. The range of symptoms produced by these agents resemble positive (delusion and hallucination), negative (avolition, apathy, and blunted affect), and cognitive (deficits in attention, memory, and abstract reasoning) symptoms of schizophrenia as well as disruptions in smooth-pursuit eye movements and prepulse inhibition of the startle response [143–150]. Moreover, administration of low doses of ketamine to patients

with schizophrenia precipitates the expression of acute psychosis incorporating symptoms that are similar in content to patients' preexisting experience [140, 151–153]. Collectively, these studies have made a strong case for an NMDA receptor deficiency in schizophrenia because they demonstrated that an NMDA receptor antagonist produces a behavioral syndrome that resembles symptoms of schizophrenia far better than dopamine agonists do [154].

NMDA receptors play an essential role in the development of neural pathways, including the critical process of the pruning of cortical connections during adolescence [155, 156], making them a likely contributor to the hypothesized developmental malfunctions in schizophrenia [157, 158]. Given the pharmacological and developmental evidence, it was suggested that a hypoglutamatergic state, probably at the level of NMDA receptors, might account for some aspects of schizophrenia, particularly the cognitive and negative symptoms that are closely associated with frontal cortical function [154, 159, 160]. During the past decade, this theory has been further modified to account for the complexity of glutamatergic transmission and its interactions with other neurotransmitter systems, especially dopamine and γ -aminobutyric acid (GABA) [161–166]. Here, we will first briefly review the main elements of the glutamate system and then discuss the evidence for a glutamatergic dysregulation in schizophrenia.

In general, glutamate receptors can be classified into two broad families: ionotropic and metabotropic receptors. Ionotropic glutamate receptors are classified into three broad subtypes according to their preferential agonists: the NMDA, kainate, and α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors. Binding of glutamate to these receptors stimulates Ca^{2+} entry into neurons through channels formed either by the receptor itself (as is the case with the NMDA receptor subtype) or by opening voltage-sensitive Ca^{2+} channels that are on the cell membrane. The AMPA receptors are composed of at least four subunits derived from a family of four genes termed *GluR1* to *GluR4*. Kainate receptors are thought to be composed of five identical subunits (homomers) derived from genes termed *GluR5* to *GluR7* and *KAI1* and *KAI2*. The NMDA receptor is a heteromeric complex composed of four or five subunits derived from seven genes, *NR1*, *NR2A* to *NR2D*, *NR3A* and *NR3B* [167]. The *NR1* subunit, which has several isoforms, is an obligate subunit. Nearly all neurons express AMPA and NMDA receptors, and it is estimated that glutamate ionotropic receptors mediate nearly 50% of all synaptic transmission in the mammalian central nervous system. The more recently discovered metabotropic glutamate receptors [168] have a distinct mechanism of action and use G-protein-coupled synaptic transduction mechanisms, similar to those used by the monoamine neurotransmitters, to indirectly regulate the electrical signaling. This mechanism is in contrast to rapid excitation and opening of ion channels by ionotropic glutamate receptors, which is a more suitable mechanism for pharmacological targets. At least eight metabotropic glutamate receptors have been cloned (termed mGlu1 to mGlu8). These receptors share no sequence homology with other known receptors in the nervous system, suggesting that they are members of a new receptor gene family. The eight subtypes of mGlu receptors are currently classified into three groups (termed groups I–III) based on amino acid sequence homology and transduction mechanisms. Group I (mGlu1 and mGlu5) metabotropic receptors activate the enzyme phospholipase C, which in turn results in the breakdown of membrane phospholipid to the second messengers inositol triphosphate or

diacylglycerol. Groups II (mGlu2 and mGlu3) and III (mGlu4, mGlu6, mGlu7, and mGlu8) metabotropic receptors downregulate the enzyme adenylate cyclase and result in reduced synthesis of the second messenger cyclic adenosine monophosphate (cAMP).

8.3.2 Pathological Evidence

In general, the direct evidence for glutamatergic involvement in schizophrenia is abundant and converges on several principles. First, abnormalities in various components of glutamatergic systems, including the NMDA receptor, have been reported in schizophrenic brain samples. Second, these abnormalities follow a region-specific pattern with the most impressive accumulation of evidence being so far reported from temporal and frontal cortices, limbic regions, and thalamus, with limited evidence found in striatum.

Several groups have reported altered densities of kainate and AMPA glutamate receptors in postmortem schizophrenic brains [169–173]. Harrison and coinvestigators reported decreases in AMPA receptor binding in CA3 and CA4 subfields of hippocampus [170, 172]. These findings are consistent with reports of reduced expression of GluR1 and GluR2 protein or mRNA levels in similar regions [172, 174–176]. In contrast to the temporal lobe regions, the reported changes in frontal cortex and striatal regions have been small [177]. Consistent decreases in AMPA GluR1 and GluR2 expression have also been reported in the thalamus [178]. Collectively, these data suggest that in schizophrenics' brains there are decreases in the expression of several AMPA receptor subunits and in AMPA receptor binding in the medial temporal lobe and the thalamus.

Several other studies have examined kainate receptor binding or mRNA levels [131, 179–183]. In general, these studies follow the same pattern of change as in AMPA receptor expression, suggesting reduced levels of expression in temporal lobe regions. Furthermore, a recent study reported increased transcript levels of GluR5 (a kainate subunit) in substantia nigra in schizophrenia [167].

Studies on NMDA receptor density in cortical, striatal, and temporal lobe structures have led to less consistent results (see [169] for a review). However, more recent data indicate that part of the earlier inconsistencies may be due to alterations in the subunit composition of NMDA receptors. The earliest report in the literature using [³H]MK801 described increased binding in the putamen but not in the frontal cortex or temporal lobe [171]. Similar increases were reported using [³H] D-aspartate [184] but another study failed to replicate the finding in putamen [180]. Studies using [³H]TCP (which, similar to MK801, binds to the phencyclidine site on the NMDA receptor complex) have also resulted in conflicting observations with either no change [185] or an increase in binding in orbitofrontal cortex being reported [186].

More recent studies have examined the expression of NMDA receptor subunits in schizophrenic brain and have reported several region-specific results. There are reports of increased temporal and PFC expression of NR1 [187–189]. However, an older study [190] had found no major changes in any of the NMDA receptor subunits in PFC with the exception of a higher ratio of NR2D to the other NR2 subunits. In the thalamus, a significant reduction in NR1, NR2A, NR2B, and NR2CR subunits have been reported [178, 191, 192]. Other reports demonstrated a downregulation of

NR1 in the superior temporal gyrus, hippocampus [182, 193], and thalamus [178] and upregulation of NR2B subunit in the superior temporal cortex [188]. A recent study also reported a decrease in NR1 subunit expression in substantia nigra [167].

Studies examining the expression of the family of metabotropic glutamate receptors have only recently begun, and although there are only a few published studies in this area [194, 195], this is likely to be an active field of research in the future. So far, an increase in mGluR5 in orbitofrontal cortex has been reported [194].

In addition to glutamate receptors, Coyle and coinvestigators [196] have reported postmortem abnormalities in the expression of the neuropeptide *N*-acetylaspartyl glutamate (NAAG), which is considered an endogenous ligand for some subtypes of glutamate receptors. This reported increase in the levels of NAAG as well as a decrease in its catabolic enzyme NAALADase in the PFC and hippocampus may reflect alteration in glutamate neurotransmission in schizophrenia [197]. Abnormalities of other indices of glutamate transmission, such as a decrease in vesicular transporter 1, have also been reported in the medial temporal cortex of schizophrenic brains [198]. In the thalamus, an increase in excitatory amino acid transporters EAAT1 and EAAT2 and vesicular glutamate transporter VGLUT2 and in the NMDA receptor-associated proteins NF-L, PSD95, and SAP102 has been reported [199–201].

Another approach has been to investigate mechanisms that indirectly affect the NMDA receptor function, including those that involve the glycine modulatory site on this receptor. Preliminary evidence suggests that the levels of endogenous agonists (glycine and D-serine) and antagonist (kynurenic acid) for this site may have been altered in schizophrenia. This includes reports of decreased serum levels of D-serine [202] and glycine [203] and increased CSF levels of kynurenic acid [204–206] in patients with schizophrenia.

Pathological evidence of abnormalities in structural organization of frontal cortices in schizophrenia may be an indirect indicator of disruption in the main mode of chemical communication (glutamatergic transmission) in this region. Accordingly, abnormalities in a range of structural parameters, including gray matter volume [207–212], cortical thickness [213], cortical gyrification [214, 215], hippocampal shape [216, 217], neocortical and hippocampal pyramidal cell size [218–226], and dendritic spine number and arborization [227–230], have been reported in schizophrenia. Furthermore, several groups have reported the presence of aberrantly located or clustered neurons in entorhinal cortex [231–233] and neocortical white matter [234–239] of schizophrenic brains, findings that fit the idea of an early neurodevelopmental problem in cortical areas. While these pathological abnormalities should be interpreted with caution because of the relatively small effect of sizes and inconsistencies in reported changes in any single parameter, together they further support the involvement of the cortical and thalamic glutamatergic system in the pathophysiology of schizophrenia.

8.3.3 Imaging Evidence

Unlike the monoamine systems, selective glutamate receptor ligands for clinical imaging studies have not been fully developed for routine use in healthy and patient volunteers [240]. As a result, most of the imaging evidence regarding a link between glutamate and schizophrenia is indirect. This includes evidence of abnormal functional

connectivity in frontotemporal cortices during working memory tasks in schizophrenic patients [241–247]. In addition, an impaired recruitment of hippocampus during a memory recollection task [248] and an abnormal frontotemporal interaction during a semantic processing task [249] have been reported in schizophrenic patients. Offering another indirect line of evidence, Kegeles et al. [250] used SPECT and proton magnetic resonance spectroscopy (MRS) to study, in normal subjects, the effect of an experimental state of NMDA receptor hypofunction (induced by ketamine) on amphetamine-induced striatal dopamine release, a measure previously reported to be enhanced in schizophrenia [60] (see Section 8.2). They found an increase in raclopride displacement, interpreted as enhanced dopamine release, by an NMDA receptor antagonist. This finding is similar to observations in schizophrenic patients and suggests that NMDA receptor hypofunction may explain the enhanced dopaminergic response to amphetamine challenge in schizophrenia.

8.3.4 Genetic Evidence

While there is limited evidence for the direct involvement of a glutamate receptor gene in schizophrenia (see [251, 252] for a review), recent genetic studies offer a novel insight for possible pathophysiological processes that converge on glutamate-related targets (see below). A linkage study with a genetically isolated African population suggested that a NR1 subunit polymorphism might be associated with predisposition to develop schizophrenia [253]. Other studies, however, have so far reported lack of association with polymorphisms for genes encoding for NR1, NR2B, GluR5, mGluR7, and mGluR8 [254–257]. So far, the most interesting link to a glutamate receptor gene has been suggested for mGluR3 (*GRM3*) in three independent association studies [258–260]. Egan and coinvestigators [258] have shown that a variation in this gene can affect performance on working memory and attention tasks and on functional magnetic resonance imaging (fMRI) activation of dorsolateral PFC and hippocampus in both schizophrenic patients and normal controls. Interestingly, the agonists of type II mGlu receptors (including mGluR2 and mGluR3) can reverse the adverse behavioral, cognitive, and electrophysiological effects of NMDA receptor antagonists [261, 262]. However, further investigation on the role of this candidate gene is required since there are reports of unaltered *GRM3* mRNA level in PFC and thalamus of schizophrenic patients [194, 195, 263].

Regardless of direct involvement of glutamate receptor genes, most of the candidate genes that have emerged from recent association and linkage studies are functionally linked to glutamatergic transmission (see [166, 264] for a review). These genes include, but are not limited to, neurogelin 1 (*NRG1*), regulator of G-protein signaling 4 (*RGS4*), *G72*, dysbindin (*DTNBP1*), *PPP3CC*, disrupted-in-schizophrenia 1 (*DISC1*), and proline dehydrogenase (*PRODH2*). All of these candidate genes may interact with the glutamatergic transmission and function at various postsynaptic levels. For example, *NRG1* regulates the expression of glutamate receptor subunits and directly activates ErbB4, a tyrosine kinase that regulates the kinetic properties of NMDA receptor [265, 266]. *RGS4* can inhibit the mGlu5 receptor transmission through negative regulation of G-protein signaling [267–269]. *G72* interacts with the enzyme D-amino acid oxidase (DAAO) (see above) that reduces the synaptic availability of D-serine through oxidizing it [270, 271]. Dysbindin recruits nitric oxide synthase (NOS), which in turn affects NMDA receptor activity [272].

PPP3CC encodes a subunit of calcineurin that is considered essential for some types of NMDA receptor-mediated plasticity [273]. Implication of these genes has prompted the suggestion that they may functionally converge at the level of microcircuit information processing, particularly involving NMDA receptor pathways [166, 264].

8.3.5 Pharmacological Evidence

It is plausible that the next generation of antipsychotic therapies may eventually emerge from current research on glutamatergic transmission. In contrast to the dopamine field that was originally derived by the effectiveness of serendipitously discovered drugs, glutamate-based therapeutics would conceptualize the efforts to translate current neuroscientific ideas into clinical treatments. However, the progress in this field has been slowed by the widespread distribution of major glutamate receptors such as NMDA or AMPA receptors and their involvement in key functions such as learning and memory, raising the concerns that drugs that directly target these receptors may be associated with serious side effects. To tackle this caveat, some researchers have attempted to use coagonists of NMDA receptor that bind to its glycine site and increase the frequency of NMDA-gated channel opening [274–278]. Basic research has indicated that the glycine modulatory site on NMDA receptor is not saturated in vivo and thus glycine and related molecules such as D-serine and D-cycloserine may be able to ameliorate the NMDA receptor hypofunction (see [279] for a review). Early clinical trials have indicated that this strategy may alleviate the negative and perhaps cognitive symptoms of schizophrenia [276, 280–285]. However, these agents do not appear to have antipsychotic efficacy and their effectiveness as adjuvant therapy remains to be established [286–289]. Notably, a recent meta-analysis of the randomized controlled trials in schizophrenic subjects showed a moderate amelioration of negative symptoms by glycine and D-serine without any significant effect on other symptoms [290]. Meanwhile, some have suggested that a positive modulation of the glycine site may best be achieved through manipulating the molecular pathways that regulate the turnover of its endogenous ligands. For example, it is known that the availability of glycine is dependent on the activity of glycine transporter 1 (GlyT1) [291, 292], while the availability of D-serine is determined by the activity of serine racemase and the degrading enzyme DAO [293]. Thus, efforts are underway to develop inhibitors of GlyT1 and serine racemase in order to increase the in vivo availability of glycine and D-serine, respectively [278, 279, 294, 295]. Another line of potential therapies that is currently under investigation is based on fine tuning glutamate transmission through metabotropic glutamate receptors [296, 297]. In this regard, one promising strategy may be based on functional potentiation of postsynaptic mGlu5 receptors that show synergistic interactions with NMDA receptors in regulation of behavior and cognition in animal studies [298–301]. Findings from these studies predict that activation of mGlu5 receptors may ameliorate the presumed state of NMDA receptor deficiency in schizophrenia. However, the rapid desensitization rate of mGlu5 receptors makes it unlikely that direct agonists of these receptors may have persistent therapeutic effectiveness. Instead, recently developed positive allosteric modulators of mGlu5 receptor function may offer a more efficacious strategy [302–304], a promise backed by recent reports in experimental models [305, 306, 306a]. Alternatively, preclinical

studies have shown that the agonists of group II mGlu receptors may inhibit the adverse effects of NMDA receptor antagonists on behavior, working memory, and PFC function [261, 262, 307], suggesting the therapeutic potential of this strategy for schizophrenia. A key finding was that NMDA receptor antagonists lead to an excessive increase in PFC glutamatergic transmission through non-NMDA receptors [308], leading to the assumption that agents such as activators of presynaptic group II mGlu autoreceptors that can block this aberrant activity may prove beneficial to relieve the presumed states of cortical malfunction. Accordingly, a recent clinical study in healthy human subjects treated with ketamine offered the first proof of concept that activation of group II mGluRs may ameliorate cognitive dysfunction in the context of NMDA hypofunction [309]. The same principle, normalizing an inappropriate pattern of cortical activity, may underlie the reported effectiveness of lamotrigine, an anticonvulsant agent with cation channel blockade properties, in ketamine-treated subjects [310, 311]. Correspondingly, preliminary reports of the advantageous effects of lamotrigine adjunctive therapy in schizophrenia have been published [312–314].

Another approach has been to develop agents that reduce the rate of desensitization and therefore potentiate the function of AMPA glutamate receptors as “cognitive enhancers” since these agents can improve learning and memory in animal models [315–318]. Preliminary results with this class of agents, called “AMPAkines,” suggest that boosting glutamatergic transmission may indeed be beneficial for the core cognitive deficits in schizophrenia [319]. However, these drugs may be in particular worthy as adjuvant to current therapies [319, 320], rather than for single-agent therapy [321].

Given that our approach to treating schizophrenia has not fundamentally changed for 50 years and the acute need to develop more efficacious drugs for treatment of nonpsychotic symptoms of schizophrenia, in particular the enduring cognitive deficits of the disease, there has been a surge of interest in developing and testing “novel” glutamatergic drugs in animal models and in human subjects. Hence, the next decade promises to be an exciting time for the field because, for the first time, drugs that are designed based on pathophysiological mechanisms and are not merely prototypes of existing neuroleptics may be developed.

8.4 CONSOLIDATING GLUTAMATE AND DOPAMINE HYPOTHESES OF SCHIZOPHRENIA

Given the dominance of the dopamine hypothesis, the original attempts to consolidate these theories focused on proving that NMDA receptor deficiency is associated with dopamine hyperactivity. Earlier release studies examining dopamine turnover or measuring the uptake of labeled dopamine showed that NMDA receptor antagonists increase the release of striatal dopamine [322–324]. This finding contributed to the first version of an integrated dopamine–glutamate theory, suggesting that NMDA receptor hypofunction may represent a paradigm that simulates the presumed dopamine hyperfunction in schizophrenia [154, 325, 326]. This interpretation, however, could not account for the fact that NMDA receptor antagonists induce a far wider range of schizophrenia-like symptoms than the dopaminergic models. Thus, the theory was modified to distinguish a role for cortical

versus subcortical glutamate–dopamine interactions for induction of negative and cognitive versus positive symptoms [50, 114, 160]. However, subsequent work using microdialysis or imaging methodologies showed that behaviorally relevant doses of NMDA antagonists do not increase dopamine release in rodents, primates, or humans [327–330]. Furthermore, behavioral studies demonstrated that the dopamine system is neither necessary [331] nor sufficient [327] for maintenance of the aberrant behavioral effects of the NMDA receptor antagonists. This and the abundance of postmortem and genetic findings supporting a role for the glutamate system in the etiology and pathophysiology of schizophrenia have led to the proposal that the primary abnormalities in schizophrenia may involve the synaptic signaling machinery in cortical regions [2, 92, 332] and that a dopaminergic abnormality may be a consequence of cortical dysregulation of dopamine neurons. Interestingly, contrary to years of assertion that the PFC stimulates dopamine neuronal activity [333, 334], recent anatomical studies have demonstrated that cortical projections do not synapse directly onto mesostriatal dopamine neurons [335]. Furthermore, stimulation of PFC neurons at physiological frequencies actually decreases dopamine release in the ventral striatum [336]. This suggests that the PFC exerts an inhibitory influence over subcortical dopamine presumably through indirect activation of GABA neurons [336, 337]. Thus, reduced glutamatergic function in the PFC may remove this inhibitory influence and lead to an abnormally overactive subcortical dopamine system in schizophrenia. Recent electrophysiological studies recording from PFC neurons in behaving rodents, in fact, show that a state of NMDA deficiency can lead to reduced burst activity of cortical neurons [338].

Given the lack of direct evidence for a dopaminergic abnormality in schizophrenia, an alternative hypothesis has been that antipsychotic drugs, which are D_2 receptor antagonists, work by modifying the function of cortical (glutamatergic) neurons [166]. A substantial body of evidence demonstrates that dopamine modulates cortical and subcortical glutamatergic transmission [339–345]. Notably, electrophysiological studies have revealed a delicate modulatory effect for dopamine on the electrical conductance of cortical excitatory neurons, that is, neither excitatory nor inhibitory, but rather is a gating effect that depends on the activity state of target neurons [341, 344, 345]. Furthermore, D_2 receptors may regulate the temporal organization of electrical activity in PFC [343]. The D_2 receptors also inhibit the release of glutamate [346, 347], suggesting that blockade of D_2 receptors by antipsychotic drugs can overcome a putative state of glutamate deficiency. In support of this mechanism, electrophysiological studies have shown that antipsychotic agents, particularly clozapine, exert positive modulatory effects on the NMDA receptor function in PFC and may attenuate the blockade of these receptors by phencyclidine [348–351]. Interestingly, a recent study in behaving animals suggests that clozapine can reverse the disruptive effects of NMDA receptor blockers on cortical firing in correlation with behavior. This reversal may be a result of fine-tuning of cortical activity as clozapine increased the activity of the neurons with low baseline firing rates and decreased the activity of neurons with higher firing rates [351a].

Another hypothesis has been that dopamine and glutamate interactions may occur at the postsynaptic level and through the intricate postsynaptic intracellular mechanisms known to mediate crosstalks between these transmitter systems [352, 353]. Taken together, these modified scenarios would explain the lack of strong

pathological and genetic evidence for the involvement of dopamine in the pathophysiology of schizophrenia despite the clinical effectiveness of dopamine-based drugs. Instead, they emphasize the importance of viewing schizophrenia as a constellation of molecular and cellular processes that may functionally converge at the circuitry level, most probably downstream from corticolimbic NMDA receptors. One implication of these models is that polytransmitter theories, incorporating interactions between dopamine, glutamate, and other major neurotransmitter systems, have replaced the existing monotransmitter theories [342]. An important example in this case is the PFC GABAergic system which has been strongly linked to schizophrenia (see [354, 355] for a review). It has been hypothesized that disruptions in GABA-mediated inhibitory tone of cortical interneurons may contribute to decrease the signal-to-noise ratio in cortical circuitry in schizophrenia [341, 342], paving the way for the sort of functional degradation that occurs in the NMDA antagonist model [338, 356].

Rapid progress in the fields of imaging, psychiatric genetics, and postmortem molecular analysis of brain tissues is likely to help continue the evolution of dopamine and glutamate hypotheses of schizophrenia. While one hopes that for a devastating disease like schizophrenia hypotheses will soon be replaced by concrete data and effective cures, the concerted efforts of researchers in conceptualizing theoretical bases of schizophrenia has been, and will continue to be, instrumental in developing a better understanding of the mechanisms underlying schizophrenic disorders and efforts to develop a new generation of more effective treatments.

9.1 GENETIC EPIDEMIOLOGY

The results of numerous family, twin, and adoption studies show conclusively that risk of schizophrenia is increased among the relatives of affected individuals and that

is the result largely of genes rather than shared environment [1–3]. In the children and siblings of individuals with schizophrenia, the increase in risk is around 10-fold and somewhat less than this in parents. The latter finding is probably explained by a reduction in the reproductive opportunities, drive, and possibly fertility of affected individuals. Five recent systematically ascertained studies report monozygotic (MZ) concordance estimated at 41–65% compared with dizygotic (DZ) concordance of 0–28% and an estimate of broad heritability of 85% [4]. The heritability of schizophrenia is one of the highest for any complex genetic disorder. To place it in perspective, it is similar to that of type 1 diabetes (72–88% [5, 6]) but greater than breast cancer (30% [7]), coronary heart disease in males (57% [8]), and type II diabetes (26% [9]).

While the twin and adoption literature leaves little doubt that genes are important, they also point to the importance of environmental factors since the concordance for schizophrenia in MZ twins is typically around 50% and heritability estimates are less than 100%. Moreover, we should also note that risks resulting from gene–environment interactions tend to be attributed to genes in most genetic epidemiological studies.

Genetic epidemiology also tells us that, like other common disorders, schizophrenia has a mode of transmission that is complex and includes the multiple-susceptibility-loci model [10, 11]. However, the number of loci, the risk conferred by each, and the degree of interaction between them remain unknown. Risch [12] has calculated that the data are incompatible with the existence of a single locus conferring a sibling relative risk (λ_s) of more than 3 and, unless extreme epistasis (gene–gene interaction) exists, models with two or three loci of $\lambda_s \leq 2$ are more plausible. It should be emphasized that these calculations are based upon the assumption of homogeneity and refer to populationwide λ_s . It is quite possible that alleles of larger effect are operating in some groups of patients, for example families with a high density of illness. However, high-density families are expected to occur by chance even under polygenic inheritance, and their existence does not prove the existence of disease alleles of large effect [11].

9.1.1 Defining Phenotype for Genetic Research

Schizophrenia displays considerable heterogeneity of symptoms, course, and outcome (see Chapter 7). It is possible that this reflects etiological heterogeneity, although if etiologically distinct subgroups do exist, we cannot yet identify them. In spite of this, structured and semistructured interviews together with explicit operational diagnostic criteria permit reliable diagnosis of a syndrome with high heritability. It should then in principle be possible to subject schizophrenia to molecular genetic analysis.

One way of refining the phenotype for genetic studies of complex traits is to define intermediate phenotypes or endophenotypes, that is, traits that are intermediate between susceptibility genes and the clinical phenotype. A number of endophenotypes for schizophrenia have been proposed based upon electrophysiology, pharmacology, psychology, or neuroimaging. Such traits are likely to be essential for understanding how variation in a proven susceptibility gene leads to the clinical phenotype. However, the use of endophenotypes for the identification of disease genes requires that the measures in question are trait, rather than state, variables and compelling

evidence from genetic epidemiology that they reflect genetic vulnerability to that disease rather than environmental factors. Promising data are accumulating for some potential endophenotypes for schizophrenia [13], but, in most cases, uncertainties remain.

The situation is further complicated by the fact that we are unable to define the limits of the clinical phenotype to which genetic liability can lead. It clearly extends beyond the core diagnosis of schizophrenia to include a spectrum of disorders, including schizoaffective disorder and schizotypal personality disorder [14, 15]. However, the limits of this spectrum and its relationship to other psychotic disorders, especially bipolar disorder, remain uncertain [16, 17]. Based upon the way the field is progressing, it seems likely that one of the earliest benefits of the identification of susceptibility genes is that the validity of current nosological categories can be further explored. Knowing the genes involved should allow us to dissect the current concept of schizophrenia and help us to understand its relationship to other diagnostic groups.

9.1.2 Are There Clues for Genetics from Epidemiology, Pathophysiology, and Neurobiology?

Epidemiological, pharmacological, and neurobiological studies have made some progress in our general understanding of schizophrenia (see other chapters in this section). The more specific hypotheses based upon abnormalities in neurotransmission, especially dopaminergic and glutaminergic, are very possibly relevant to some of the overt clinical manifestations of the disorder, but with few exceptions, molecular genetic studies predicated on these hypotheses have met with disappointing results. Moreover, many of the leading hypotheses involve rather vague concepts such as neurodevelopment, synaptic dysfunction, and aberrant neuronal connectivity. These concepts are so broad that it is difficult to use them to confidently implicate specific pathophysiological processes or to specify compelling candidate genes. These problems with hypothesis-based approaches have encouraged a number of groups to apply so-called positional genetic approaches for the simple reason that these do not depend upon knowledge of disease pathophysiology.

9.2 MOLECULAR GENETIC STUDIES

9.2.1 Linkage Studies

In contrast with several other common disorders like breast cancer, Alzheimer's disease, Parkinson's disease, and epilepsy, no genetically simple subtypes of schizophrenia have yet been discovered. The results of linkage studies in schizophrenia have often seemed to be disappointing, with positive studies usually falling short of stringent "genomewide" levels of significance and abundant failures to replicate. This is probably attributable to a combination of small genetic effects, inadequate sample sizes, and heterogeneity of causative loci between and within populations [18]. However, as more than 20 genomewide studies have been reported, and sample sizes increased, some consistent patterns have emerged. Linkages that reached genomewide significance on their own according to the criteria set forth by Lander

and Kruglyak [19] or those that have received strong support from more than one sample are shown in Figure 9.1.

Recently, two meta-analyses of schizophrenia linkage have been reported. Each used different methods and obtained overlapping but somewhat different results. The study of Badner and Gershon [20] supported the existence of susceptibility genes on chromosomes 8p, 13q, and 22q, while that of Lewis et al. [21] most strongly favored 2q. The latter study also found that the number of loci meeting the aggregate criteria for significance was much greater than expected by chance ($p < 0.001$), with evidence for susceptibility genes on chromosomes 5q, 3p, 11q, 6p, 1q, 22q, 8p, 20q, and 14p.

The linkage data therefore support the predictions made by Risch [12] on the basis of genetic epidemiological findings; that is, the evidence is consistent with the existence of multiple susceptibility alleles of moderate effect. Nevertheless, it is also possible that loci of larger effect exist in specific samples of large multiply affected families. Of course, the proof that a positive linkage is correct comes when the disease gene has been identified. Happily, recent years have finally seen a number of breakthroughs in post-linkage positional cloning.

Figure 9.1 Ideogram showing chromosomal regions of linkage to schizophrenia and candidate genes that may be associated. Vertical bars denote regions where evidence for linkage has been found in more than one study (green) and where linkage has reached genomewide significance (red) according to the criteria of Lander and Kruglyak [19]. Arrows (red) identify regions where chromosomal abnormalities are involved with schizophrenia. The chromosomal positions of the major candidate genes discussed in this chapter are also displayed. (See color insert.)

9.2.2 Positional Candidate Genetics

Previously, the economics and practicalities of hunting a susceptibility gene within a linked chromosomal region dictated that one should have virtually definitive evidence that the linkage was a true positive. With recent improvements in our knowledge of genome anatomy and in genome analysis technology, the task of positional cloning has been transformed and favors bolder endeavors. These considerations, together with the convergence of some positive linkage findings, have led to a number of detailed mapping studies of linked regions which have in turn implicated specific genes. However, the quality of the data has been variable and a number of putative susceptibility genes have yet to be clearly replicated. Here, we focus on the genes where, at the time of writing, there are published follow-up studies or where we are aware of data that allow judgment about whether the gene is likely to be a true positive. In making these judgments, we have primarily been influenced by the strength of the genetic evidence for association to the clinical phenotype. We have given no weight to claims that a SNP (single-nucleotide polymorphism) is functional or that the gene has plausibility by virtue of patterns of expression or participation in relevant pathophysiological pathways. These are key properties of true susceptibility variants, but the number of SNPs in genes that meet the above criteria is so vast that such evidence cannot be used to prop up weak genetic findings. We have also given little weight to associations with putative endophenotypes, be they based on electrophysiology, pharmacology, psychology, or neuroimaging or performed in humans or modeled in animals. Such studies are likely to be essential for understanding how variation in a proven susceptibility gene leads to the clinical phenotype. However, for the *de novo* identification of disease genes, unless it is known with a very high degree of confidence that an endophenotype in question does actually index genetic risk for disorder, a considerable amount of uncertainty inevitably must accompany its use.

9.3 CANDIDATE GENES

9.3.1 Dystrobrevin Binding Protein 1 (DTNBP1)

Chromosome 6p22.3 is one of the most consistently reported linkage regions for schizophrenia (Fig. 9.1). After detailed studies designed to follow up their original findings of linkage in Irish pedigrees, Straub and colleagues [22] reported evidence for genetic association between schizophrenia and markers in the *DTNBP1* or dysbindin gene which maps to this region. Significant associations to markers and haplotypes have subsequently been found by several other research groups in independent populations of schizophrenics (e.g., [23–29]) which have included samples that do not show significant linkage to the 6p region. Although not unexpectedly there have also been some samples in which association has not been found [9, 26, 30], the evidence now strongly favors *DTNBP1* as a susceptibility gene for schizophrenia and possibly a more general psychotic phenotype [32]. However, the associated haplotypes have differed between studies, suggesting possible allelic heterogeneity or, alternatively, population differences in the linkage disequilibrium structure across the gene [23].

As yet, no causative variant has been identified, and the absence of associated nonsynonymous alleles after systematic mutation detection of the exons [25] suggests that disease susceptibility depends upon variation affecting messenger RNA

(mRNA) expression or processing. The latter possibility is *directly* supported by evidence for as-yet-unknown cis-acting alleles affecting *DTNBP1* expression in the human brain [33] that may reside upon haplotypes reported to be overrepresented in schizophrenics [37] and also by two recent studies showing reduced levels of expression of the mRNA [34] and protein [35] in post-mortem brain samples from patients with schizophrenia. This hypothesis needs to be tested by studying the relationship between the various associated haplotypes and RNA abundance, but identification of the risk variant, or variants, will require high-resolution work, including the identification and analysis of all polymorphisms across *DTNBP1*, possibly in multiple populations.

Dysbindin binds both α - and β -dystrobrevin, which are components of the dystrophin glycoprotein complex. The dystrophin complex is found in the sarcolemma of muscle but is also located in postsynaptic densities in a number of brain areas, particularly mossy fiber synaptic terminals in the cerebellum and hippocampus. Its location initially suggested that variation in *DTNBP1* might confer risk of schizophrenia by mediating effects on *postsynaptic* structure and function [22]. However, dysbindin has been shown to be part of a complex that influences the activity of presynaptic intracellular vesicles [36]. Talbot and colleagues [35] have recently shown that the presynaptic dystrobrevin-independent fraction of dysbindin is reduced in schizophrenic brain within certain intrinsic glutamatergic neurons of the hippocampus. Talbot and colleagues also observed that in schizophrenic brain reduced dysbindin expression was associated with increased expression of the vesicular glutamate transporter type 1. Taken together with the further observation that reduction in *DTNBP1* expression [27] is associated with reduced glutamate release *in vitro*, the findings so far are compatible with the hypothesis that *DTNBP1* might confer risk by altering presynaptic glutamate function.

9.3.2 Neuregulin 1

Neuregulin (*NRG1*) was first implicated in schizophrenia in an Icelandic sample [38]. Association analysis across a schizophrenia linkage region on 8p21–22 revealed highly significant evidence for association between schizophrenia and a multimarker haplotype at the 5' end of *NRG1*. Strong evidence for association with the same at-risk haplotype was subsequently found in a large sample from Scotland [39] and weakly replicated in a U.K. sample [40]. Further positive findings have emerged from Irish [41], Bulgarian (Kirov et al., unpublished), Chinese [30, 42–44], and South African [30] samples that largely implicate the 5' region of the gene. However, some negative findings have also been reported [30, 45–47], notably in Irish, Japanese, U.S. and South African populations. Only the two deCODE studies and our own U.K. study have implicated the specific Icelandic haplotype, perhaps reflecting differences in the LD (linkage disequilibrium) structure across *NRG1* in European and Asian samples (e.g., [44]) and emphasizing the fact that the associated variants, even if true positives, are not the causative ones.

Despite detailed resequencing [38], it has not yet proven possible to identify specific susceptibility variants, but the Icelandic haplotype points to the 5' end of the gene, once again suggesting that altered expression or perhaps mRNA splicing might be involved. It is even formally possible at this stage that *NRG1* is not itself the susceptibility gene, as intron 1 contains another expressed sequence [41] whose

function is unknown. However, insofar as it is possible to model schizophrenia in animals, behavioral analyses of *NRG1* hypomorphic mice support the view that the association is related to altered *NRG1* function or expression [48]. More direct evidence suggesting that altered expression, and in particular altered expression of the ratios of different *NRG1* transcripts, might be involved in the pathogenesis of schizophrenia is also beginning to accumulate [49].

Just as for *DTNBP1*, the pathological pathways by which altered *NRG1* function might lead to schizophrenia are unclear. *NRG1* encodes many mRNA species, which in turn translate into numerous proteins with multifarious functions. At the time it was implicated as a susceptibility gene for schizophrenia, it was thought to encode around 15 proteins with a diverse range of functions in the brain, including cell–cell signaling, ErbB receptor interactions, axon guidance, synaptogenesis, glial differentiation, myelination, and glutamatergic neurotransmission [50]. Any, or perhaps a combination of several of these, could be involved. Moreover, to further complicate matters, a number of novel exons that encode novel *NRG1* isoforms whose functions are currently unknown have recently been identified [51].

9.3.3 D-Amino Acid Oxidase (*DAO*) and D-Amino Acid Oxidase Activator (*DAOA*)

Chumakov and colleagues [52] undertook association mapping in the schizophrenia linkage region on chromosome 13q22–34. They found evidence for association to markers around two novel genes they termed *G72* and *G30* in French Canadian and Russian populations. *G72* and *G30* are overlapping but transcribed in opposite directions. Little is known of *G30* other than that it is transcribed in the brain. *G72* is a primate-specific gene expressed in the caudate and amygdala. Using yeast two-hybrid analysis, Chumakov and colleagues reported evidence for physical interaction between *G72* and *DAO*. *DAO* is expressed in human brain where it oxidizes D-serine, a potent activator of NMDA glutamate receptors. Coincubation of *G72* and *DAO* in vitro revealed a functional interaction between the two, with *G72* enhancing the activity of *DAO*, and consequently, *G72* has now been named *DAOA*. In the same study, *DAO* polymorphisms were shown to be associated with schizophrenia in the Canadian sample only, and analysis of *DAOA* and *DAO* variants revealed modest evidence for a statistical interaction between the loci and disease risk. Given the three levels of interaction, the authors concluded that both genes influence risk of schizophrenia through a similar pathway and that this effect is likely to be mediated through altered NMDA (*N*-methyl-D-aspartate) receptor function.

Associations between *DAOA* and schizophrenia have subsequently been reported in samples from Germany [53], China [54, 55], and both the United States and South Africa [30] and in Askenazi Jews [56] and a small sample of very early onset psychosis subjects from the United States [57]. As before, and conceivably for similar reasons, there is no consensus concerning the specific risk alleles or haplotypes across studies. At present, the published genetic evidence in support of both of these genes is weaker than for *DTNBP1* and *NRG1* and stronger for *DAOA* than *DAO*; indeed, so far, only a German group [53] has reported (weak) evidence in favor of *DAO*. Nevertheless further research is clearly required given reports of association of *DAOA* with bipolar disorder and psychosis [57, 58] suggesting that the gene might be a susceptibility locus for some aspect of psychopathology that is present in both schizophrenia and bipolar disorder.

9.3.4 Regulator of G-Protein Signaling 4

RGS4 maps to a putative linkage region on chromosome 1q22, but it was targeted for genetic analysis [59] following a microarray-based gene expression study in which decreased *RGS4* expression was found in schizophrenic postmortem brain [60]. Evidence for association between schizophrenia and haplotypes at the 5' end of the gene was found in two samples from the United States, and while not providing significant evidence alone, inclusion of a sample from India added to the overall level of support [59]. Analysis of a Brazilian sample has not provided support [61], but positive findings with both single markers and haplotypes have been reported in samples from the United Kingdom and Ireland [62–64]. The level of support for each has been modest and the pattern of association different between samples. Currently, our view is that the evidence for *RGS4* is interesting but far from convincing, and the results of a meta-analysis being coordinated by the original group to which the present authors have contributed are now keenly awaited.

In terms of possible mechanisms of action, *RGS4* is a negative regulator of G-protein-coupled receptors. The relationship between RGS molecules and receptor function is a promiscuous one, but of possible interest to schizophrenia is the evidence that *RGS4* modulates activity at certain serotonergic [65] and metabotropic glutamatergic receptors [66], while its own expression is modulated by dopaminergic transmission [67]. Moreover, *RGS4* interacts with *ErbB3* [68], which may be of relevance as *ErbB3* is a *neuregulin 1* receptor whose expression is downregulated in schizophrenic brains [50]. Interestingly, variation between *RGS4* has also recently been associated with reduction in dorsolateral prefrontal cortex gray matter volume [69], a finding of possible relevance given that reduction in prefrontal gray matter is well documented in schizophrenics (e.g., [70]).

9.3.5 Others

Association has been claimed between schizophrenia and *CAPON* (C-terminal PDZ domain ligand of neuronal nitric oxide synthase) [71], *PPP3CC* (protein phosphatase 3, catalytic subunit) [72], *TRAR4* (trace amine receptor 4) [73], and enthoprotin [74], which map respectively to putative linkage regions on 1q22, 8p21.3, 6q23.2, and 5q33. As discussed in the original articles, each of these genes can be plausibly related to candidate pathophysiologies of schizophrenia, but at the time of writing, we are not aware of any robust replication data to support these hypotheses, although *CAPON* has received some support in a Chinese sample [75].

9.4 CHROMOSOMAL ABNORMALITIES

9.4.1 Catechol-*O*-Methyltransferase (*COMT*)

There have been numerous reports of associations between schizophrenia and chromosomal abnormalities [76], but with two exceptions none provides convincing evidence for the location of a susceptibility gene. Several studies have shown that adults with 22q11 deletions have a high risk for schizophrenia [77–79], with the largest study of adult patients to date ($n = 50$) estimating this at 24% [79]. The deletion cannot account for a high proportion of schizophrenic cases [80], but reports

of linkage to 22q11 [20, 21] suggest that variants in genes mapping to this region might contribute to more typical cases. Current candidates include *COMT*, proline dehydrogenase (*PRODH*), and zinc finger- and DHHC domain-containing protein 8 (*ZDHHC8*).

COMT has been intensively studied because of its key role in dopamine catabolism. Most studies have focused upon a valine-to-methionine change at codon 158 of the brain predominant membrane-bound form of COMT (MB-COMT) and codon 108 of the soluble form (S-COMT). The valine allele confers higher activity and thermal stability to COMT [81] and has been fairly consistently associated with reduced performance in tests of frontal lobe function [82, 83]. The results in schizophrenia have been mixed, with recent meta-analyses [84] reporting no overall evidence for association.

Since the preparation of the meta-analysis, an Israeli study of over 700 cases reported strong evidence for association between haplotypes, including the *val158* allele and two flanking, non coding SNPs [85]. As in an earlier study [86] the evidence from haplotypes was stronger than for the valine allele alone, suggesting that *COMT* may well be a susceptibility gene for schizophrenia but that the effect is not attributable to the *val/met* variant. We have been unable to replicate association with any of the SNPs or haplotypes, including the *val/met* polymorphism in a study of more than 2800 individuals, including almost 1200 schizophrenics [87], but two other groups [81, 88] have recently reported rather different haplotype associations at *COMT* in Irish and U.S. samples, respectively. As for the Israeli study, haplotypes carrying the *val158* allele exhibited stronger evidence for association than did that allele alone, while in the second study, the strongest findings included markers spanning the 3' end of the armadillo repeat deleted in the velocardiofacial syndrome gene (*ARVCF*). The latter has also been implicated in an earlier study [86] and its transcribed genomic sequence overlaps with *COMT* [89]. While the picture is confused, we consider that the evidence does not support a role for *val/met 158* in susceptibility to schizophrenia, although a small effect cannot be excluded, nor can a role in phenotype modification. However, it remains a strong possibility that variation elsewhere in *COMT*, or *ARVCF*, confers susceptibility.

9.4.2 *PRODH*

PRODH is another functional candidate gene given that a loss-of-function mutant mouse exhibits behavioral abnormalities in sensorimotor gating that are analogous to those observed in schizophrenics [90] and because proline dehydrogenase influences the availability of glutamate. Evidence in favor of association between SNPs in *PRODH* has been reported [91, 92], but arguing against this, we were unable to replicate either of these findings in large case-control and family-based association samples ([93] and G. Kirov et al., unpublished). Moreover, discrepancies in allele labeling between the two positive studies reduces, though does not abolish, the support provided to the former by the latter. One of the studies [91] also suggested association between a number of *PRODH* missense variants and schizophrenia while a separate study reported both heterozygous deletion of the entire *PRODH* gene in a family that included two schizophrenic subjects and missense variants in 3 of 63 schizophrenic patients studied [94]. However, we [93] and (in a follow-up of their own study [94]) Jacquet and colleagues [95] observed a range of missense mutations to be

equally common in schizophrenic cases and controls, while *PRODH* deletions were reported not to be associated with schizophrenia in a very large sample of Japanese subjects [96]. Interestingly, while the study of Jacquet and colleagues [95] failed to provide evidence for their hypothesis of association between schizophrenia and hyperprolinemia (a consequence of loss-of-function *PRODH* mutations), they did find evidence for association between schizoaffective disorder and *PRODH*. Whether this is a chance finding or a finding of relevance to the discrepancies between existing data is at present unknown.

9.4.3 ZDHHHC8

Finally, there is evidence that a SNP (rs175174) in *ZDHHHC8*, a gene which encodes a putative transmembrane palmitoyl transferase, might directly confer susceptibility to schizophrenia by affecting the splicing of *ZDHHHC8* mRNA [97]. Interestingly, association was only observed in females [97]. The genetic evidence was not strong but gained support from the observation of a similar sexual dimorphism in mice homozygous for a knockout of this gene, with females but not males, displaying the phenotypes modeling aspects of schizophrenia. Unfortunately, of the two published attempts at replication so far, one found the opposite allele to be associated in a Han Chinese sample and no evidence for a gender effect [98] and the other, in a relatively large Japanese case-control study, failed to find any association [99]. Recently in collaboration with colleagues in Bonn [100] we investigated rs175174 in four schizophrenia samples including a Bulgarian proband/parent sample (474 trios) and three case-control panels of European origin (1028 patients, 1253 controls). The results did not support the hypothesis that genetic variation at rs175174 is associated with increased risk for schizophrenia nor did they suggest the presence of gender-specific differences. Overall, the current evidence fails to support the hypothesis that SNP rs175174 in intron 4 of *ZDHHHC8* directly influences susceptibility to schizophrenia. However, although unlikely in our opinion, it remains possible that susceptibility to schizophrenia is conferred by another genetic variant or variants in *ZDHHHC8* that are in LD with rs175174 in the U.S. and South African samples studied by Mukai and colleagues [97] and the Han Chinese sample studied by Chen and colleagues [98] but not in the samples from Bulgaria, Germany, Poland, Sweden, and Japan [99, 100].

9.4.4 DISC1

The other major finding based upon a chromosomal abnormality comes from an extended pedigree in which a balanced chromosomal translocation (1;11)(q42;q14.3) showed strong evidence for linkage to a fairly broad phenotype consisting of schizophrenia, bipolar disorder, and recurrent depression [101]. The translocation was found to disrupt two genes on chromosome 1 which were on this basis called disrupted in schizophrenia 1 and 2 (*DISC1* and *DISC2* [101, 102]). No known genes mapped within the chromosome 11 disruption. *DISC2* contains no open reading frame and may regulate *DISC1* expression via antisense RNA [102]. Interestingly *DISC1* and 2 are located close to the chromosome 1 markers implicated in two Finnish linkage studies [103, 104] (Fig. 9.1). It has been suggested that truncation of *DISC1* in the translocation family might contribute to schizophrenia by affecting

neuronal functions dependent upon intact cytoskeletal regulation such as neuronal migration, neurite architecture, and intracellular transport [105, 106]. While these are interesting hypotheses, it is important to remember that translocations can exert effects on genes other than those directly disrupted. For example, there are several mechanisms by which a translocation can influence the expression of neighboring genes. Thus, in order to unequivocally implicate *DISC1* and/or 2 in the pathogenesis of schizophrenia, it is necessary to identify in another population mutations or polymorphisms that are not in strong LD with neighboring genes but which are associated with schizophrenia. Four published studies have attempted to do this. Negative studies were reported by the Edinburgh group that originally identified *DISC1* and 2 [107] and by a group who focused on the 5' end of the gene in a large Japanese sample [108]. In contrast, positive findings have been reported in a large Finnish study [109] while haplotypic associations were found in U.S. samples with schizophrenia, schizoaffective disorder, and bipolar disorder [110]. At present, the genetic evidence in favor of *DISC1* as a susceptibility gene is gaining momentum but, in our view, is not yet compelling. Interestingly, if *DISC1* is a true susceptibility gene, it appears to confer risk for phenotypes including schizoaffective disorder, bipolar disorder, and major depression as well as schizophrenia [110]. Given the range of phenotypes associated with the translocation in the original study, despite its name, this should not be that surprising.

9.5 FUNCTIONAL CANDIDATE GENES

There is a huge schizophrenia candidate gene literature consisting of negative findings or positive findings that have either not been replicated or have seemed so unconvincing that there have been no attempts to do so. While most of the reported positives are unlikely to stand the test of time, neither can we conclude that any gene has been effectively excluded, given that most have not been studied exhaustively in large samples through a combination of detailed sequencing of exons, introns, and large regions of 5' and 3' flanking sequences combined with exhaustive genotyping. However, meta-analyses do at least suggest that the dopamine receptors *DRD3* [111] and *DRD2* [112] and the serotonergic receptor *HTR2A* [113] might confer risk. The effect sizes, if any, are extremely small [odds ratio (OR) < 1.2] and difficult to confirm, but if the associations are true, the findings provide some support for the view that altered dopaminergic and serotonergic function might be a primary event in schizophrenia susceptibility. If the putative associations are the result of LD between the assayed markers and the true susceptibility variant, it is possible that the latter might contribute somewhat more, depending upon the degree of LD between the two.

Despite the accumulating evidence for abnormalities of glutamatergic neurotransmission in schizophrenia, by and large, analysis of glutamatergic genes as functional candidates for schizophrenia has failed to produce consistent positive findings. However, recently claims have been made that variation in *GRM3* (the gene encoding metabotropic glutamate receptor type 3) might confer risk to schizophrenia. *GRM3* was first implicated in a case-control study of German patients. However, as only one SNP was significantly associated in one out of the three groups of patients studied [114], the authors concluded against a role for this gene in schizophrenia. Fujii and colleagues [115] genotyped six SNPs in a small case-control sample from

Japan. They found significant association with one SNP and a three-marker haplotype containing this SNP. Egan et al. [116] genotyped seven SNPs, including the two implicated in the previous reports, in a family based association study. Weak evidence for overtransmission to cases was observed for one SNP; however, this was not one of the SNPs implicated previously and the result failed to replicate in a second sample. A haplotype including this SNP was also overtransmitted to cases, but this finding has yet to be replicated. The authors presented further data relating the single putatively associated *GRM3* SNP to cognitive, fMRI, MRS, and neurochemical variables. They argued that these data converge on the conclusion that *GRM3* affects prefrontal and hippocampal physiology, cognition, and risk for schizophrenia by altering glutamate neurotransmission. However, the genetic data implicating *GRM3* as a susceptibility gene for schizophrenia remain weak, although the findings of Egan and colleagues [116] clearly suggest that further study is warranted.

9.6 FUNCTIONAL IMPLICATIONS OF SUSCEPTIBILITY GENES

In our view the evidence now strongly implicates *DTNBP1* and *NRG1* as susceptibility genes for schizophrenia, while the data for *DAO*, *DAOA*, *DISC1*, and *RGS4* are promising but not yet compelling. Even in the most convincing cases, the risk haplotypes appear to be associated with small effect sizes [odds ratio (OR) < 2.5] and, although this is difficult to determine, do not appear to fully explain the linkage findings that prompted each study. This could suggest that the associated polymorphisms/haplotypes are only in weak LD with the true pathogenic variants, that the linkages reflect variation at more than one susceptibility site in the same gene (or in multiple genes in the area of linkage), or that in some cases, despite the statistical evidence, the associations are spurious. Work in this area highlights how difficult it can be to determine what comprises a clear replication of associations that are based on LD, especially those based upon associations with haplotypes rather than single markers [117]. It is by no means certain that support requires the same pattern of association to be obtained or, conversely, that a negative finding can be regarded as a failure to replicate only if the associated allele or haplotype from the original study is examined. Detailed follow-up studies, including de novo mutation detection and detailed genotyping in large samples drawn from different populations, with the aim of answering these questions are now required.

For most geneticists, the purpose of disease gene identification is to enhance our understanding of pathogenesis. Thus it is now important that we identify the specific mechanisms by which the recently implicated genes alter the risk of schizophrenia and the molecular and cognitive processes that link these primary events to psychopathology. Already, it has been noted that several of the genes encode proteins that potentially impact on the function of glutamatergic synapses which might therefore be the location of the primary abnormality [118–120]. The possible importance of synaptic abnormalities in schizophrenia had already been recognized [121] and the recent genetic data suggest that there might at last be convergence between the genetics of schizophrenia and its neurobiology. However, there are several reasons for remaining cautious. First, the genetic evidence is not yet definitive and we have not identified the specific pathogenic variants, much less the pathogenic

mechanisms. Second, if we consider the two best-supported genes, *NRG1* encodes proteins with multiple functions of potential relevance to alternative hypotheses of schizophrenia, for example, aberrant myelination [50] while the function(s) of dysbindin are still obscure. Third, the widely held assumption that schizophrenia is a heterogeneous disorder with more than one core pathophysiology may well be correct. If this is so, then attempts to fit the data into a unified theory, while attractive and parsimonious, will ultimately prove futile. It is therefore vital that there is no letup in the hunt for novel schizophrenia genes, the finding of which will allow us to test existing and to generate novel hypotheses of pathogenesis.

9.7 CONCLUSIONS

Molecular genetic studies of schizophrenia are built upon the firm foundations of reliable diagnostic methodology and a wealth of genetic epidemiological data. The fact that most, if not all, disease genes apparently have only moderate or small effect sizes has proved challenging, as it has in the study of other common diseases. However, the sample and technological resources combined with the reagents generated by the Human Genome Project have begun to permit what appears finally to be genuine progress. A number of potential regions of linkage and two associated chromosomal abnormalities have been identified, and accumulating evidence favors several positional candidate genes, although in no case has the causative variant(s) been identified. These findings suggest that the positional genetic approach to schizophrenia is at last bearing fruit. As in most respects the task of positional cloning is becoming simpler, there are grounds for considerable optimism that genetics will continue to provide crucial insights into the aetiology of schizophrenia.

10.1 INTRODUCTION

Schizophrenia is a syndrome characterized by psychotic symptoms (hallucinations, delusions, thought disorder) and cognitive impairment, with a prevalence rate approaching 1% worldwide. Over 100 years of neuropathology research has failed to identify a pathomnemonic lesion in the brains of schizophrenic patients. Nevertheless, important facts dictating the direction of a number of neuropathological studies have arisen from research efforts in related areas.

First and foremost is the evidence that schizophrenia has a clear genetic component. Results from twin and adoption studies show a heritability estimate

for schizophrenia of 70–90% [1–3]. However, analysis of recurrence risk estimates in families with one or more affected individuals clearly argues against schizophrenia being a single-gene disorder even with the possibility of incomplete penetrance [4]. Alternatively, the mode of transmission for schizophrenia is complex and multifactorial with the possibility of a number of genes conferring varying degrees of susceptibility. With this in mind, efforts have been directed at identifying allelic variants in genes that may confer increased risk for schizophrenia.

The identification of allelic variation in susceptibility genes that increase the risk for schizophrenia is only a first step in elucidating the pathophysiology. Exactly how susceptibility genes lead to schizophrenia remains largely unknown. A neurodevelopmental hypothesis argues that schizophrenia is the result of in utero events that lead to changes in neurogenesis, neuronal migration, and synaptic plasticity [5]. An alternative hypothesis of neurodegeneration proposes that schizophrenia is the result of neuronal loss or gliosis that occurs during aging [6]. For the most part, the latter theory has languished in part due to studies showing that such pathological hallmarks are only found in schizophrenia associated with dementia [6]. Still a third line of inquiry suggests that schizophrenia is a progressive developmental disorder with aberrant neuronal pruning during development that continues into early adulthood [7]. A better understanding of the pathophysiology associated with schizophrenia susceptibility genes may elucidate which, if any, of these hypotheses is correct.

Studies on the neurochemical basis of schizophrenia implicate many neurotransmitter systems, including dopamine, glutamate, γ -aminobutyric acid (GABA), and acetylcholine. During the last five decades, the dopamine system has been the central focus of schizophrenia research. The focus on dopamine relies largely on the fact that antipsychotics used to treat schizophrenia correlate with their ability to block D_2 receptors [8, 9]. A revised “dopamine hypothesis” posits that a hypofunction of the D_1 receptors in the prefrontal cortex (PFC) coexist with increased subcortical dopamine associated with D_2 receptors [10–12]. An alternative hypothesis based on the psychomimetic properties of phencyclidine (PCP), an *N*-methyl-D-aspartate (NMDA) receptor antagonist, has implicated the glutamate neurons and is supported by neuroimaging and postmortem studies [13, 14]. A number of other postmortem studies implicate GABA inhibitory neurons in the neuropathology of schizophrenia [15–18]. Last but not least, both muscarinic (M) and nicotinic acetylcholine receptors [19] have also been postulated in the pathophysiology of schizophrenia [20, 21]. Again the identification of schizophrenia susceptibility genes may be the best evidence that multiple neurotransmitter systems are implicated in schizophrenia.

Identification of allelic variation in genes that increase risk for schizophrenia may implicate specific neurotransmitter systems and pathological processes. Moreover, this knowledge may elucidate molecular pathways involved in the pathophysiology of the syndrome that may alter both our diagnostic systems and lead to new therapeutic targets.

10.2 APPROACHES TO IDENTIFY SUSCEPTIBILITY GENES IN SCHIZOPHRENIA

With the high heritability estimates for schizophrenia, genetic researchers have postulated that there are a number of susceptibility genes, each conferring increased

risk for the disorder. The search for the genetic component of schizophrenia has primarily employed linkage analysis and association studies.

The aim of linkage studies is to identify regions of the genome that are cotransmitted with the disease in the affected individual but not in unaffected family members. Using polymorphic DNA markers distributed along each chromosome it is determined which DNA marker is cotransmitted with the disease due to its close physical proximity to the disease-causing gene. Once a candidate chromosomal locus harboring the disease gene is identified, fine mapping of this putative disease-linked region is then performed in order to pinpoint the disease-causing gene. Although this technique has been used with great success in identifying distinct chromosomal regions in the genome that may play a role in schizophrenia (Table 10.1), there are a number of limitations to linkage analysis. Due to the lack of a large number of

TABLE 10.1 Schizophrenia Susceptibility Genes Identified by Linkage Analysis and Association Studies

families with multiple affected individuals, ascertainment differences, broad phenotypic definitions, ethnic and environmental variations, and sparse polymorphic DNA markers, it is not surprising that linkage studies have not been an unmitigated success in the identification of schizophrenia susceptibility genes [22].

Chromosomal location by linkage analysis and fine mapping of the region followed by association studies of the genes present in this chromosomal region are designed to identify alleles of certain genes that are more common among individuals with the disorder than in the general population. Association studies are typically carried out by selecting specific polymorphisms in candidate genes that are thought to be correlated with the disease based on location and/or function and then determining the allelic frequency in affected versus unaffected individuals. Although useful, association studies are limited by the fact that the actual disease-causing polymorphisms have to be identified and then tested in affected versus unaffected individuals [23]. Since little is known about the neurobiology of complex mental disorders, picking truly relevant causative genes for association studies is inherently challenging. This difficulty is further increased when interpreting polymorphisms in noncoding regions that are not ultimately translated to a protein product. Moreover, inadequate patient–control matching, small sample size, and differences in allelic frequencies between different populations further contribute to the observed discrepancies in findings on the same gene by different groups.

Another method used to identify disease genes is analysis of cytogenetic abnormalities found more often in patients than in unaffected individuals. These chromosomal abnormalities such as translocations and large-scale deletions/duplications may be helpful if the affected chromosomal region harbors genes that contribute to the disease when their function is disrupted. Although there have been numerous reports on chromosomal anomalies associated with schizophrenia [24, 25], only two have provided convincing evidence that is supported by linkage data. The first is the identification of *DISC1* by a balanced reciprocal translocation [(1;11)(q42;q14.3)] in a large Scottish family with multiple individuals affected with schizophrenia and other psychiatric disorders [26, 27]. The second finding of interest is the association of schizophrenia with velocardiofacial syndrome (VCFS), which is caused by interstitial deletions of chromosome 22q11. In addition to a large number of physical anomalies associated with VCFS, patients with this disorder have a dramatic increase in the risk of psychosis, particularly schizophrenia [27–31]. It has been hypothesized that the deleted chromosomal region in VCFS may harbor schizophrenia susceptibility genes.

As is evident, over the last decade a large number of association studies have implicated numerous genes in the pathophysiology of schizophrenia. As an alternative to discussing all of these implicated genes in-depth, for the purpose of this postmortem brain studies review, we will concentrate on genes that fulfill the following criteria: First, the gene should be located on a chromosomal region implicated by linkage analysis. Second, there should be at least three positive association studies with the gene and schizophrenia in ethnically homogeneous populations [32]. Third, there should be data from postmortem molecular studies on expression of messenger RNA (mRNA) or protein available for the gene, particularly from regions of the brain implicated in schizophrenia. Finally, the gene product should have some functional significance for schizophrenia either at the time of neuronal development or in adult brain; that is, it would be expected to relate to prevalent schizophrenia hypotheses such as the neurodevelopmental hypothesis and

dopamine hypothesis. Based on these criteria we will review the following genes in detail: *COMT*, *DTNBP1*, *GRM3*, *DISC1*, *NRG1*, *GAD1*, and *RGS4*. Some of the linkage and association studies implicating these genes are listed in Table 10.1.

10.2.1 *COMT*

Catechol-O-methyl transferase (*COMT*) is a 27-kb gene located on chromosome 22q11 and encodes for a protein crucial for the enzymatic degradation of dopamine. This gene is composed of six exons: exons 1 and 2 are noncoding while exon 3 contains codons for two distinct promoters giving rise to two functionally different transcription products [33]. The short, 1.3-kb human mRNA produces the soluble isoform (S-COMT) while the longer 1.5-kb human mRNA produces the membrane-bound isoform (MB-COMT) [34]. Of these, the MB-COMT predominates in the human brain while S-COMT is found peripherally [33, 35, 36]. In the human brain, COMT mRNA is highly expressed in the prefrontal cortex, striatum, and midbrain [35] while electron microscopy studies have revealed the protein to be present on dendrites in these regions [37, 38].

A number of single-nucleotide polymorphisms (SNPs) in the *COMT* gene have been found to be associated with schizophrenia [39–43]. Only two of these polymorphisms affect COMT enzymatic activity [36]. A P₂ promoter SNP may have an effect on COMT expression as reflected in enzymatic activity in lymphocytes [36].

By far, the SNP with the most effect on the COMT expression and enzymatic activity is a missense mutation in exon 4 of the *COMT* gene yielding a nonsynonymous amino acid change from Val-Met at either position 108 in S-COMT or 158 in MB-COMT [44]. Although the *val* allele is associated with lower mRNA [40] and protein expression [36], it has higher enzymatic activity than the *met* allele [36]. Earlier studies of COMT enzymatic activity in brain found no differences between schizophrenics and controls [45, 46]. More recent postmortem findings also indicate that mRNA and protein expression levels of COMT are unaltered in the dorsolateral prefrontal cortex of schizophrenics [35, 36, 47]. However, an altered mRNA distribution pattern is observed in this region in schizophrenics when compared to controls [35]. Since the difference in frequency of the Val/Met allelic variation between schizophrenic cases and controls is small (approximately 6%), a large number of postmortem brains ($n = 272$) would be necessary to observe a significant difference in the schizophrenics [36]. As a consequence it is possible that the postmortem studies mentioned above were underpowered to observe a significant difference in COMT between schizophrenics and controls.

As dopamine transporters are expressed in low levels in the PFC [48] and thus are thought to play only a small role in synaptic dopamine reuptake in the PFC [49, 50], COMT may be crucial in terminating dopamine neurotransmitter function in PFC. Moreover, those individuals with the homozygous *val* allele in COMT may have lower cortical dopamine levels. Low levels of dopamine in the PFC alters downstream signaling pathways and initiates the synthesis of dopamine subcortically by an observed increase in nigral tyrosine hydroxylase (TH) mRNA in postmortem tissue [51–59].

In addition to COMT and TH, the level of dopamine receptors (DRD2) have also been examined in postmortem schizophrenia in an effort to better understand the role dopamine plays in disease pathology. The psychomimetic effect of dopamine agonists

and antipsychotic antagonism at DRD2 [9, 60–62] led to numerous studies of the D₂ receptor in postmortem human brain of schizophrenics and controls. While many studies have reported alterations in the level of D₂ receptors in postmortem tissue [63–68], much of the earlier findings have been challenged by the lack of isoform-specific antibodies and receptor-specific ligands as well as being confounded by antemortem neuroleptic treatment. Even in vivo neuroimaging receptor studies in drug-naïve patients, which report an increase of D₂ receptors in the striatum [69], have not been confirmed by others [70–73]. Currently, there is a general consensus from postmortem and neuroimaging studies that D₂-like receptors, particularly the D₂, are increased in the striatum [74, 75], although the etiology of this increase is probably secondary to neuroleptic treatment. A number of association studies have linked DRD2 with schizophrenia [76–82]; however, due to methodological problems in population stratification, the validity of these studies remains doubtful.

10.2.2 *DTNBP1*

DTNBP1 is a 140-kb gene located on 6p22.3, one of the best-established regions to have emerged from linkage studies of schizophrenia (Table 10.1). *DTNBP1*, is composed of 10 exons and encodes dysbindin 1 protein. Dysbindin mRNA is expressed widely in the brain and has been detected in the frontal and temporal neocortices, hippocampus, caudate, putamen, nucleus accumbens, amygdala, thalamus, and midbrain of the adult human brain [83]. These anatomical expression data are salient because regions such as frontal cortex and hippocampus are strongly implicated in schizophrenia.

Although the precise molecular function of dysbindin protein in the brain has not been determined, dysbindin binds to dystobrevins, which are components of the dystrophin-associated glycoprotein complex (DCG) [84]. DCG is a multiprotein complex that is required for normal functioning of muscle cells, and several DCG-like complexes have been identified in postsynaptic densities in the brain [85]. Alterations of these complexes have been implicated in the cognitive impairment that commonly occurs in patients with Duchenne muscular dystrophy (DMD) [86, 87]. Interestingly, the absence of dystrophin in the *mdx* mouse model of DMD results in altered distribution of dysbindin in the cerebellum [88]. Dysbindin has also been found to be a component of the biogenesis of lysosome-related organelles complex (BLOC)-1 [89], which may play a role in schizophrenia and will be subsequently discussed in greater detail.

Postmortem brain studies have found expression levels of dysbindin mRNA levels to be reduced in the dorsolateral prefrontal cortex of schizophrenics compared to controls [83], and SNPs in three prime untranslated region (3'UTR), intron 3, 5'UTR, and 5' flanking region significantly impact dysbindin mRNA levels in PFC [83]. Dysbindin protein levels are also significantly reduced in the postmortem hippocampus of schizophrenic patients [90]. Dysbindin mRNA levels in human brains are reduced by cis-acting polymorphisms, and a schizophrenia risk haplotype was also found to be associated with reduced *DTNBP1* expression in the frontal, parietal, or temporal cortices [91, 92].

Downregulation of dysbindin expression has been found to cause reduced phosphorylation of AKT1 [93]. The serine–threonine protein kinase gene encoded by AKT1 is 32.8 kb in size, located on chromosome 14q32 spanning 14 exons.

AKT1-GSK-3 β (glycogen synthase kinase 3 β) is a target of lithium and has been implicated in bipolar disorder [94]. In the developing nervous system AKT1 is a critical mediator of growth factor-induced neuronal survival. In situ histochemistry of mouse brain during normal development determined that embryonic AKT1 mRNA levels were high throughout the entire neuroaxis. The level of expression gradually decreased during postnatal development and into adulthood [95]. AKT1 protein levels are reduced in lymphocytes, hippocampus, and PFC of schizophrenics [96]. Reduced phosphorylation of GSK-3 β , which is a target of AKT1, was also detected in lymphocytes and frontal cortex lysates [96]. GSK-3 β mRNA levels are also reduced in dorsolateral prefrontal cortex (DLPFC) of schizophrenic patients versus controls [97]. Based on these findings, AKT1 may play a role in neurodevelopment and altered postnatal levels of AKT1 and its downstream molecular targets may contribute to increased risk for schizophrenia.

10.2.3 *GRM3*

GRM3 (human metabotropic glutamate receptor subtype 3) is mapped to chromosome 7q21–22 [98] and is considered a positional and functional candidate gene for schizophrenia based on a genomewide scan [99]. *GRM3* is approximately 220 kb in size and contains six exons [100]. The protein product of the gene is assembled into a membrane-bound receptor coupled to second-messenger pathways and allows for a decrease in glutamate release [101, 102]. *GRM3* is widely distributed in the DLPFC, thalamus, and hippocampus. However, neither the mRNA nor protein expression was altered in schizophrenics relative to controls in any of these regions [103–105]. In our laboratory, in vivo functional magnetic resonance imaging (MRI) testing has revealed that an intronic SNP in the *GRM3* gene is associated with poor hippocampal and prefrontal functions [106]. This study also reports that the same intronic SNP is associated with a lower mRNA expression in the postmortem brain tissue of the excitatory amino acid transporter 2 (EAAT2), a modulator of synaptic glutamate levels. Additionally, a number of splice variants of *GRM3* have been detected in the human brain [107].

10.2.4 *DISC1*

DISC1 is a 414.3-kb gene located on chromosome 1q42.2 and consists of 13 exons. As mentioned above, *DISC1* was originally identified as a candidate gene for schizophrenia in a large Scottish family, in which a balanced translocation involving chromosomes 1 and 11 was strongly linked to schizophrenia, schizoaffective disorder, bipolar affective disorder, and recurrent major depression [26]. In this family, carriers of the translocation were found to have reduced P300 amplitude, which is observed in some patients with schizophrenia [27]. Subsequent association studies identified a number of polymorphisms in the *DISC1* gene associated with schizophrenia and affective disorder (Table 10.1).

In the adult mouse brain, *DISC1* is expressed widely including the olfactory bulb, cortex, hippocampus, hypothalamus, cerebellum, and brain stem. During development, *DISC1* protein is detected at all stages, from embryonic day 10 (E10) to 6 months old, with two significant peaks of protein expression of one of the *DISC1* isoforms at E13.5 and postnatal day 35 [108]. Interestingly, these time points

correspond to periods of active neurogenesis and puberty in the mouse. These results suggest that *DISC1* may play a critical role in brain development, lending support to the neurodevelopmental hypothesis of schizophrenia [108]. Although the precise function of *DISC1* in the brain is unknown, a number of *DISC1*-interacting partners have been identified, including FEZ1, NUDEL, and LIS1, which are known to play a role in neuronal development and functioning. Postmortem studies have detected altered subcellular distribution of *DISC1* in patients with psychosis and alcohol/substance abuse, with increased ratios of nuclear to cytoplasmic *DISC1* protein levels in patients [109]. Although *DISC1* mRNA expression is unchanged in postmortem human brains of patients with schizophrenia, the expression of *DISC1*-interacting proteins NUDEL, FEZ1, and LIS1 mRNA is significantly reduced in schizophrenic tissue in both the DLPFC and hippocampus [110]. Altered interactions between *DISC1* and its binding partners have also been investigated in order to understand more accurately the biology of *DISC1* as a schizophrenia susceptibility gene.

10.2.5 *NRG1*

Neuregulins are a family of widely expressed growth and differentiation factors. The neuregulin gene family consists of four genes (*NRG1* to *NRG4*). *NRG1* is approximately 1.125 Mb in size and contains at least 21 exons and 9 potential promoters [111]. Thus far six distinct isoforms and at least 16 splice variants have been reported [111, 112]. While *NRG2*, *NRG3*, and *NRG4* are found only in adult tissue, *NRG1* type I isoform is expressed early in development, type II is expressed late in development, and type III is expressed in peripheral sensory and motor neurons as well as in the brain [113]. The newly discovered isoform types IV–VI [111] have an unknown anatomical distribution and functions. In the developing and adult human brain, *NRG1* mRNA and protein are present in the hippocampus, cerebellum, neocortex, and some subcortical nuclei [114]. *NRG1* type I expression is increased in the DLPFC of schizophrenic patients, while the type II and III levels remain unchanged [115]. Recently, our laboratory has found 5' SNPs in the *NRG1* gene that are associated with a change in the mRNA expression of type I and IV isoforms [116]. Postmortem microarray studies also report a significant reduction in the level of ErbB3 receptors, through which neuregulins indirectly exert their biological effect, in the prefrontal cortex of schizophrenics [117, 118]. However, preliminary in situ hybridization studies done in our laboratories using an ErbB3 probe could not confirm the previous findings [119].

10.2.6 *GAD1*

Glutamic acid decarboxylase (GAD) is the rate-limiting enzyme that converts glutamic acid to GABA, an inhibitory neurotransmitter in the brain. *GAD1* gene is 45 kb in size, contains 16 exons [120], and is mapped to chromosome 2q31 [121]. Alternative splicing of this gene results in two products, the predominant 67-kD form and a less abundant 25-kD form. GAD67 is concentrated in interneurons and neurons that fire tonically [122] and is involved in the nonvesicular release of GABA [123].

A number of postmortem studies have reported reduced GAD67 mRNA and protein in PFC of schizophrenic patients [15, 17, 18]. On the contrary, GAD67

mRNA was found to be unaltered in the hippocampus of schizophrenic patients [124]. However, one study has found an increase in GAD67 mRNA in the DLPFC [125]. Besides alterations in GAD67, ligand binding and autoradiography studies demonstrate that GABA_A receptors are upregulated in the cingulate cortex, PFCs and hippocampus of schizophrenics [126], while the short isoform of GABA_A γ subunit is downregulated in the DLPFC [127]. This, in addition to other studies on GABA_A receptor binding and immunoreactivity [16, 18, 128–135], provides strong evidence for an overall hypofunction of the GABAergic system.

10.2.7 *RGS4*

Regulator of G-protein signaling 4 (*RGS4*) is a 110-kb gene located on chromosome 1q23.1 spanning 16 exons. *RGS4* is involved in neuronal differentiation and is under dopaminergic regulation [136, 137]. Using microarray analysis *RGS4* mRNA expression was found to be reduced in the PFC in schizophrenics and controls [138]. These studies were confirmed by in situ hybridization in PFC [138]. Post-mortem studies on expression of brain *RGS4* mRNA levels detected highest levels in the cortical layers, with moderate levels observed in the parahippocampal gyrus. Inner layers of the frontal cortex, which is implicated in schizophrenia, also showed dense labeling [139]. Given these findings, *RGS4* continues to be an interesting candidate gene for schizophrenia.

10.3 MOLECULAR INTERACTIONS OF SCHIZOPHRENIA SUSCEPTIBILITY GENES

As discussed in the previous sections, the neuropathology of schizophrenia involves a number of susceptibility genes. Many of these susceptibility genes, alone, may exert only a small effect on the disease pathology but working via molecular partners may converge to share a common pathway leading to disease. In the past, much of the attention had been focused on convergent anatomical pathway involving neurotransmitters such as dopamine, glutamate, and GABA. In this section, our attention is focused on those susceptibility genes that have been shown to interact through molecular partners in animal models or artificial in vitro systems. This will then be followed by our hypotheses of how these interactions may play a role in schizophrenia with evidence from postmortem studies whenever available.

10.3.1 *DISC1*

As mentioned earlier, *DISC1* was identified by a chromosomal translocation in a large Scottish family and is considered a susceptibility gene for schizophrenia by a number of association studies. In an effort to understand the cellular function of *DISC1*, yeast-two hybrid studies have been used to identify molecular interactors of *DISC1*. It was found that *DISC1* has numerous binding partners, including NUDEL, FEZ1, ATF4/5, MAP1A [140–142]. NUDEL is a component of a pathway involved in cytoplasmic dynein movement and is involved in neurofilament assembly, neuronal migration, and development of neurite morphology [143–148]. Overexpression of truncated *DISC1* protein inhibits neurite outgrowth in PC12 cells, suggesting

that the DISC1–NUDEL complex may be involved in neuronal outgrowth [141, 148, 149]. The predicted peptide product resulting from the Scottish translocation removes the interaction domain for NUDEL. The defective DISC1–NUDEL complex may be a cause of neurodevelopmental abnormalities in schizophrenia [150]. Recently, it has been shown that NUDEL oligopeptidase activity is under tight regulation through binding to DISC1 since a mutation very close to the DISC1 binding site of NUDEL abolishes this activity [151]. Interestingly, NUDEL cleaves a number of neuropeptides in vitro, some of which have previously been implicated in the pathophysiology of schizophrenia, including neurotensin (NT) (reviewed in [152, 153]). Postmortem studies have revealed increased NT levels in the frontal cortex [154] and decreased NT binding in the entorhinal cortex in schizophrenic patients compared to controls [155]. NT receptor agonists may be potential antipsychotics; thus inhibition of NUDEL could lead to increase in local concentration of NT, which may have an antipsychotic effect [151]. Cell culture studies in cortical neurons have found evidence that DISC1 may colocalize with mitochondrial markers and that its subcellular targeting is independent of the NUDEL binding site [149]. Hayashi et al. have also demonstrated that DISC1 and NUDEL bind in a neurodevelopmentally regulated manner and form a trimolecular complex with another protein, lissencephaly 1 (LIS1). LIS1 is involved in neuronal migration and corticogenesis. Although the function of this complex is currently unknown, it is thought to play a role in dynein-mediated motor transport [151].

Another interacting partner of DISC1 is the fasciculation and elongation protein zeta-1 (FEZ1), which is a mammalian homolog of the *Caenorhabditis elegans* UNC-76 protein, involved in axonal outgrowth and fasciculation. Miyoshi et al. demonstrated that DISC1 participates in neurite extension through its C-terminal interaction with FEZ1 [156]. The chromosomal location for FEZ1 was previously implicated in a schizophrenia linkage analysis, although results from different populations vary in significance [157]. A modest association between schizophrenia and FEZ1 polymorphisms has been detected in a subset of Japanese patients [158].

An interesting hypothesis is that altered expression of DISC1 and/or its molecular partners NUDEL, FEZ1, and LIS1 may underlie its pathogenic role in schizophrenia and explain its genetic association [110]. Although DISC1 mRNA expression is unchanged in postmortem human brains of patients with schizophrenia and there is no association with previously identified risk SNPs, the expression of NUDEL, FEZ1, and LIS1 mRNA is significantly reduced in schizophrenic tissue in both the DLPFC and hippocampus and the expression of each gene showed association with a high-risk DISC1 polymorphism [110]. These data implicate genetically linked abnormalities in the DISC1 molecular pathway in the pathophysiology of schizophrenia. Given its role in brain development and plasticity via its interaction with a number of different proteins, *DISC1* remains a candidate gene for schizophrenia and an understanding of its exact mechanistic role in neuronal pathways may shed more light on the disease.

10.3.2 *DTNBP1*

Over the last decade the involvement of *DTNBP1* gene, which encodes dysbindin protein, with schizophrenia has been demonstrated by a large number of association studies and several postmortem findings. However, only recently have we begun to

understand the role of dysbindin in the brain and the biological pathways that may be affected by disruption of *DTNBP1* function.

Dysbindin overexpression and knockdown experiments using rat cortical cells suggest that dysbindin regulates the expression of synaptosomal-associated protein 25 (SNAP25) and synapsin I proteins in the presynaptic machinery [93, 158]. SNAP25 is a molecular component of the SNARE (soluble *N*-ethyl-maleimide-sensitive factor attachment protein receptors) protein complex, which is involved in intracellular vesicle trafficking and neurotransmitter release [159]. Synapsin I is localized to synaptic vesicles that are both docked and located away from the plasma membrane [159]. Reduction in protein levels of SNAP25 in the frontal cortex [160] and synapsin I in the hippocampus [161] has been reported in patients with schizophrenia, although other studies have found no change in SNAP25 [162]. Dysbindin also influences extracellular glutamate levels and glutamate release [93]. As discussed earlier, hypofunction of the glutamatergic neurotransmitter system has been implicated in schizophrenia [163].

Numakawa et al. reported that overexpression of dysbindin protected cortical neurons from cell death upon serum deprivation [93, 163]. This effect was mediated through the phosphoinositol 3 (PI3)–kinase–AKT signaling pathway. Downregulation of dysbindin expression caused reduced phosphorylation of AKT [93]. Independently, impaired PI3–kinase–AKT signaling in schizophrenia has also been observed in the PFC [96]. Reduced dysbindin expression in the schizophrenic brain [83, 90] may contribute to the impairment in AKT signaling. Disrupted dysbindin–AKT signaling might cause increased cell vulnerability and neuronal loss in vulnerable brain regions leading to the onset of schizophrenia symptoms [93]. These data establish a role for dysbindin in regulating neuronal cell viability.

Biogenesis of lysosome-related organelles complex-1 (BLOC1) is a ubiquitously expressed aggregation of interacting proteins required for the biogenesis of specialized lysosome-related organelles. This complex is linked to the secretory and endocytic pathways for cellular protein and lipid trafficking [164]. BLOC1 is comprised of several interacting proteins, including pallidin, muted, cappuccino, and dysbindin. Several of the genes that make up the BLOC1 complex are defective in the genetic disorder called Hermansky–Pudlak syndrome (HPS) [165–167]. Mutations in dysbindin cause a form of HPS called HPS7 [89]. A mouse model for HPS, the Sandy mouse, has a deleted *DTNBP1* gene and expresses no dysbindin [89]. This mouse model could be a powerful tool for investigating the function of dysbindin in the brain in vivo. Although the precise biological role of dysbindin in the BLOC1 complex is still unknown, it might be involved with endocytic vesicle docking and fusion. Presynaptic protein expression, glutamate release, AKT phosphorylation, and neuronal viability may also be assessed in vivo using this mouse model.

10.3.3 *NRG1*

Rodent studies have shown *NRG1* to function in a converging neurochemical pathway with glutamatergic, cholinergic, and GABAergic receptor systems [168–172]. As molecules located intracellularly, membrane bound, and released into the synapse, neuregulins exert their effects by acting as ligands for three receptors, ErbB2, ErbB3, and ErbB4, which are tyrosine kinases belonging to the epidermal

growth factor (EGF) receptor-related family [173]. The ErbB4, in particular, has been shown to be associated with postsynaptic density-95 (PSD-95) and NMDA receptors [174]. PSD-95, like the NMDA receptor subunits, is altered in schizophrenia [175–177] and is reported to enhance NRG1 signaling by ErbB4 dimerization [178]. Additional evidence for a molecular interaction between NRG1 and NMDA receptors has been shown in cerebellar granule cell culture, where the more biologically active β_1 isoform of NRG1 increases the levels of the NR2C subunit of the NMDA receptors [169]. More recently, the same isoform has been shown to cause ErbB dimerization resulting in increased intracellular Ca^{2+} and activation of extracellular regulated kinase (ERK) in the pyramidal neurons of the rat PFC. This downstream cascade is then thought to enhance the actin depolymerization, leading to internalization of NR1 subunits, downregulation of NMDA receptors, and a decrease in NMDA receptor-mediated current [168]. Mice lacking one copy of the *NRG1* gene showed decreased NMDA receptor binding and behavioral features related to schizophrenia [179]. These results are suggestive of the hypothesis that polymorphisms in the *NRG1* gene may lead to deficits in glutamate signaling, offering an explanation of the concept of glutamate hypofunction in schizophrenia.

Neuregulins were initially discovered as acetylcholine receptor inducing activity at the neuromuscular junction, but less is known about their effect on brain nicotinic acetylcholine receptors (nAChRs). Both high- and low-affinity nAChRs are reported to be decreased in the hippocampus, thalamus, and PFC of schizophrenics [19, 180–184]. In cultured hippocampal neurons, the NRG1 isoform β_1 was shown to increase presynaptic neurotransmitter release and to increase the number of surface membrane α_7 nAChRs [171]. Although the exact mechanism is unknown, the upregulation of nAChRs by NRG1 is presumed to occur via intracellular cascade involving ErbB4 receptors due to the colocalization of both of these receptors onto GABA interneurons in the hippocampus [174, 178, 185]. Another isoform of NRG1, the type III, is a membrane-bound bidirectional molecule which is thought to also alter nAChRs. When the extracellular portion of this isoform binds ErbB4 receptors, an intracellular cascade occurs in both the NRG1- and ErbB4-expressing neurons. Back signaling, which occurs in the NRG1-expressing neuron, is accompanied by proteolytic release and translocation of NRG1 intracellular domain into the nucleus, leading to changes in gene expression and resistance to apoptosis [186]. This back signaling in sensory neurons stimulates a redistribution of the nAChR α_7 from a diffuse somatodendritic location to a punctate axonal distribution [187]. In support of this, heterozygous mice of type III isoform have deficits in prepulse inhibition with a decrease in α_7 -subunit binding [188]. Concurrently, our own postmortem studies lend support for the interaction of NRG1 and nAChRs by the finding that 5' NRG1 SNPs identified in the original disease haplotype [179] are associated with altered α_7 -subunit receptor binding in the human DLPFC [189].

The immunoglobulin (Ig) NRG isoform has been shown to increase levels of the β_2 -subunit protein of the GABA receptors in cerebellar granule cell culture [172]. Furthermore, binding of NRG1 with ErbB4 receptor kinase is necessary for upregulation of GABA receptors [172, 190]. Because the β_2 subunits are responsible for targeting the whole receptor to the cell surface [191, 192], Rieff and colleagues [172] suggest that NRG1 may be responsible for the total number of functional receptors at the postsynaptic terminal. In contrast, infusion of the Ig isoform of NRG1 decreases the mRNA expression of the GABA_A α subunits in hippocampal

slices [193]. This report suggests that NRG1 may cause a downregulation of the GABAergic synaptic activity. The variability in the regulation of receptor subunits reviewed above indicates the diversity of the functions served by NRG1 in various brain regions. Most importantly in schizophrenia, the search should be focused on methods to elucidate the function of NRG1 in those brain regions known to be involved, such as the hippocampus, DLPFC, and midbrain.

10.4 CONCLUSIONS

Schizophrenia is a devastating neuropsychiatric disorder the genetics of which has been under extensive investigation for several decades. Despite being an exceedingly complex disease in terms of both etiology and pathogenesis, recent research is finally shedding light on schizophrenia susceptibility genes. Linkage analysis using families with multiple affected individuals has identified regions of the genome that are cotransmitted with the disease and may harbor genes involved in the pathogenesis of schizophrenia. To narrow the chromosomal regions implicated by linkage analysis, association studies using candidate gene analysis have identified a number of genes that may increase susceptibility to schizophrenia. Postmortem brain studies of these genes (such as *COMT*, *DTNBP1*, *GRM3*, *DISC1*, *NRG1*, *GAD1*, and *RGS4*) suggest that there are at least four neuronal systems implicated in the pathophysiology of schizophrenia. (1) Genes such as *COMT*, *GRM3*, and *GAD1* involve dopamine, glutamate, and GABA neurons, and it is conceivable that convergent interactions between these genes may be abnormal in schizophrenia. (2) *DTNBP1*, which encodes dysbindin protein, is involved in the presynaptic machinery and influences extracellular glutamate levels. Dysbindin influences cellular secretory and endocytic pathways responsible for protein and lipid trafficking through its involvement with the BLOC1 protein complex. (3) *DISC1* and its binding partners *FEZ1*, *NUDEL*, and *LIS1* are involved in cytoplasmic dynein movement, neurofilament assembly, neuronal migration, and neurite morphology and may play a role in the neurodevelopmental deficits observed in schizophrenia. (4) Neuregulins, encoded by *NRG1*, are involved in the maintenance of synaptic plasticity by regulating excitatory (glutamate, ACH) and inhibitory (GABA) neurotransmitters, and a disruption in their function, particularly during development, may contribute to schizophrenia.

Although the precise neurobiological cause of schizophrenia continues to be unknown, the abundance of evidence regarding susceptibility genes for schizophrenia cannot be dismissed. Susceptibility genes may provide important insights into the pathogenesis of schizophrenia. Identification of the molecular and cellular mechanisms that link susceptibility genes to the neurobiological functioning of the brain continues to be a major focus of research. It is conceivable that of the multitude of genes expressed in the brain, some of the susceptibility genes identified would have an effect on one another by either direct molecular binding or indirect upstream functioning. As evidence for the functioning of the various susceptibility genes increases, it may be determined that these genes operate in a convergent molecular pathway affecting neural development and synaptic plasticity. The disruption of multiple genes within this pathway may lead to the development of schizophrenia. Such a convergent biochemical pathway may also be an attractive target for therapeutic intervention.

Despite tremendous advances in schizophrenia research, numerous questions remain unanswered. Future studies are needed to analyze the abundance, distribution, developmental expression patterns, and perhaps most importantly molecular function and abnormalities in schizophrenia susceptibility genes. Data from these studies will not only offer insights into the functions of numerous neurobiological pathways in healthy individuals but also provide a mechanistic link between the genetics and the neurobiology of schizophrenia and other mental illnesses. Further identification of new schizophrenia susceptibility genes, dissection of the molecular pathways involved, discovery of the underlying causative defect in the schizophrenic brain, and ultimately development of better therapeutic strategies are important future goals of schizophrenia research that can be advanced by the study of postmortem brains.
